When diagnosed acutely, the acute PT dislocation can be maintained in a reduced position by a cast. Recurrent or chronic dislocation requires surgical stabilization by soft-tissue or bony reconstruction, or both. Longitudinal ruptures associated with chronic subluxation of the peroneal tendons may respond to a period of immobilization. Surgical treatment requires the identification and correction of all pathoanatomic features in addition to the debridement and repair of the longitudinal tendon rupture.

PT pathology has a tendency to evade diagnosis, especially in the acute setting. Clinical findings are very similar to that of a lateral ankle ligament sprain. Furthermore, peroneal tendon injury can occur concomitantly with lateral ankle ligament injury.

**ASSESSMENT**

The patient with acute PT dislocation complains of pain over the course of the PTs as well as the lateral border of the fibula. The patient may offer a history of forceful, passive, dorsiflexion of the foot and the detection of a “pop” at the time of injury. Many patients are able to describe accurately the translation of the tendon out of the peroneal groove. The tendon typically reduces spontaneously. Often, the patient presents after the condition becomes recurrent or chronic. Examination of the acute injury reveals swelling and tenderness behind the lateral malleolus (18, 26, 27). This is in contrast to the inversion lateral ankle sprain, which is associated with tenderness anterior to the lateral malleolus. Observation of the contralateral extremity may reveal asymmetrical physiologic subluxation. With the foot held in a plantarflexed and everted position, active dorsiflexion may result in apprehension, subluxation, and even dislocation. Dislocation is typically quite painful and is not elicited as a routine part of our examination. Gentle palpation of the PTs at the peroneal groove while the foot is taken through active circumduction may reveal the presence of nodule formation or snapping. Complete the examination with evaluation of lateral ankle ligament stability.

Patients with partial longitudinal tears of the peroneus brevis tendon associated with chronic subluxation present with acute or chronic lateral ankle pain localized to the retrofibular region. This pain may be associated with intermittent or persistent swelling, a recurrent “popping” sensation, or lateral ankle instability. Examination of the lateral ankle reveals mild to moderate swelling over the course of the peroneal tendons at the peroneal groove. Palpation of the region while the ankle is actively circumducted reveals nodule formation and possibly a “popping” phenomenon. Resisted ankle dorsiflexion may confirm the presence of physiologic subluxation of the peroneal tendons. Resisted manual motor testing may reproduce pain as well as weakness of the respective muscles. Once again, lateral ankle instability must be ruled out.

Routine radiographic evaluation after acute PT dislocation rarely demonstrates an avulsion fracture off the rim of the lateral malleolus (Fig. 118.6). Obtain stress views if lateral ankle instability is an associated finding. For cases that present a diagnostic dilemma, use MRI to detect tenosynovitis, partial or complete ruptures, subluxation, dislocation, competency of the superior peroneal retinaculum, the presence of a large distal peroneus brevis muscle insertion, the competency of lateral ankle ligaments, and internal derangement of the ankle and subtalar joints.

**CLASSIFICATION**

The pathoanatomic classification developed by Eckert and Davis (7) and subsequently modified by Oden (30) is based on the type of superior peroneal retinaculum injury (Fig. 118.7). In a type I injury, the superior peroneal retinaculum remains in continuity with the periosteum overlying the lateral border of the fibula; the tendons translate out of the peroneal groove and dissect beneath the periosteum, forming a false pouch. In the type II injury, the superior peroneal retinaculum is disrupted by an anterior tear. The type III injury is marked by an avulsion fracture off the posterior fibular margin. Finally, the type IV injury is defined by a posterior tear of the superior peroneal retinaculum.

**PREOPERATIVE MANAGEMENT**

Treat a single, acute dislocation of the peroneal tendons with a well-fitted, non-weight-bearing, short-leg cast applied with the foot in slight plantarflexion. Window the cast over the peroneal tendons at the peroneal groove. Place one-quarter to one-half inch of felt padding over the tendons and reduce the window. Instruct the patient to adjust the thickness of the felt pad for comfort. Immobilize the foot for 6 weeks, at which time, the stability of the peroneal tendons should be checked. An additional 4 weeks of casting may be necessary. Rehabilitation focuses on motion, strength, and proprioception. Occasionally, the patient is able to detect recurrent dislocation within the cast. These patients, as well as all patients with recurrent or chronic dislocation, will not respond to nonsurgical treatment methods (1, 15, 23, 24, 25, 26 and...
The treatment for partial longitudinal tear of the peroneal tendon is initially symptomatic. Treatment includes decreased activity, application of ice, and oral nonsteroidal anti-inflammatory agents. Patients that fail to respond require enforced rest with a weight-bearing cast. A taping program may allow continued athletic activity.

Before surgical exposure, the prediction of pathologic findings associated with peroneal tendon dislocation is very difficult. Therefore, it is impossible to anticipate the exact nature of the surgical repair and reconstruction. The patient must be prepared for debridement of the peroneal tenosynovium; excision of excessive distal peroneus brevis muscle insertion; resection of an anomalous peroneal tendon such as the peroneus quartus; deepening of the peroneal groove; imbrication and reconstruction of the superior peroneal retinaculum; and finally, debridement, repair, or tenodesis of the peroneal tendons. Failure to address contributing pathology or concomitant injury, may result in the persistence of symptoms. An MRI and a computed tomography (CT) scan can be used to delineate pathologic findings further, but these are not used for routine evaluation of peroneal dislocation or partial longitudinal tears.

OPERATIVE TECHNIQUES

Repair and Imbrication of the Superior Peroneal Retinaculum

- Utilizing a general or regional anesthetic and a proximal thigh tourniquet, make an L-shaped incision over the course of the peroneal tendons. Limit the initial exposure to 6 cm, with the majority of the incision proximal to the tip of the lateral malleolus. If dissection is carried distal to the lateral malleolus, take care to avoid the sural nerve and its communicating branch, which occasionally is found crossing the course of the peroneal tendons.
- Expose the superior peroneal retinaculum and verify its integrity by manipulation of the foot and ankle. When present, resect a 1 cm cuff of superior peroneal retinaculum and underlying synovial sheath intact.
- Resect peroneus brevis muscle that lies within the peroneal groove off the tendon. At this point, dislocate the peroneal tendons. Debride and repair partial longitudinal tears as described below. If the bony peroneal groove appears shallow or convex, a deepening procedure is indicated.

Figure 118.8. Treatment of peroneal tendon dislocation with a groove-deepening procedure. (Redrawn from Arrowsmith SR, Fleming LL, Allman FL. Traumatic Dislocation of the Peroneal Tendons. Am J Sports Med 1983;11:142, with permission.)

- Make a longitudinal incision through the overlying periosteum and expose the underlying cancellous bone by elevating an osteoperiosteal flap. Deepen the bony groove by removing the cancellous bone, replacing the osteoperiosteal flap, and smoothing the remaining cancellous surfaces with bone wax. Reduce the tendons and their excursion and stability by passive motion of the foot and ankle.
- At this point, repair and imbricate tears of the superior peroneal retinaculum. In the more common situation in which the superior peroneal retinaculum and the lateral fibular periosteum are elevated off the lateral border of the fibula, several pathoanatomic features must be addressed. First, obliterate the false pouch created by elevation of the lateral fibular periosteum. Accomplish this by curettage of the overlying lateral fibula. Next, advance the superior peroneal retinaculum into multiple drill holes placed through the posterolateral border of the fibula. Use multiple nonabsorbable sutures to complete a tight reconstruction. Finally, advance the remaining superior peroneal retinaculum and lateral fibular periosteum posteriorly, and repair them under the underlying reconstruction. This procedure obliterates the false pouch, and advances and reconstructs the superior peroneal retinaculum.
- Once the repair is complete and its integrity verified, reapproximate the subcutaneous tissue with absorbable suture and close the skin with nylon or skin clips. Immobilize with the foot and ankle with a compression dressing in neutral position.
- Postoperative management: At 10 days after surgery, apply a removable cast boot for non-weight-bearing ambulation. Teach range-of-motion exercises. At 6 weeks after surgery, begin weight bearing, as well as proprioception and strengthening exercises. Gradually resume activities once local swelling and warmth have resolved.

Repair of Longitudinal Peroneal Tendon Rupture

- Using a general or regional anesthetic and a proximal thigh tourniquet, expose the superior peroneal retinaculum as described in the previous section. Again, use provocative maneuvers to reproduce subluxation or dislocation.
- Next, incise the superior retinaculum posterior to the posterolateral border of the fibula. Leave a cuff of tissue attached to the fibula for subsequent repair and imbrication. Initially, complete the exposure to the tip of the fibula. Perform a complete synovectomy and tenolysis. When present, resect a distal insertion of the peroneus brevis muscle. Carefully retract and inspect each tendon.
- If the initial exploration is negative, extend the exposure distally over the course of the peroneal tendons. Leave a 1 cm cuff of superior peroneal retinaculum and synovium intact inferior to the tip of the fibula to act as a pulley.
- Debride partial longitudinal tears with associated flailization to normal tendon. After debridement, if the remaining tendon appears functional, repair the longitudinal tear with running Polydioxanone (PDS; Ethicon, Inc., Wayne, NJ) or nylon suture. If the tendon appears flattened, it may be tubularized with a running suture. If after debridement the remaining tendon does not appear to be functional, perform a tenodesis between the peroneus brevis and longus tendons proximal and distal to the peroneal groove, and sharply excise the pathologic section of tendon. At this point, take care to establish that the tendons demonstrate full excursion and stability within the peroneal groove. Instability must be addressed with the techniques described in the previous section.
- Close the peroneal sheath with a running nylon suture. Repair the subcutaneous tissue and close the skin with nylon suture or skin clips. Apply a compression dressing with the foot and ankle immobilized in a neutral position.
- Postoperative management: Ten days after surgery, apply a removable cast boot, and begin non-weight-bearing ambulation and range-of-motion exercises. At 6 weeks after surgery, progress to weight bearing to tolerance with the cast boot and institute a proprioception and strengthening program. Gradually resume activities when local warmth and swelling resolve.

GENERAL REHABILITATION

After the completion of a nonoperative or operative treatment program, focus rehabilitation on ankle and subtalar range-of-motion, ankle and subtalar stability, peroneal motor strengthening, and finally, lower extremity proprioception. Resume full athletic activity only when local warmth and swelling have resolved and the patient demonstrates full pain-free range of motion without evidence of tendon or joint instability.

COMPLICATIONS

Occasionally, surgical exploration of the peroneal tendons fails to reveal significant pathologic findings. At this point, do not hesitate to extend the exposure distally beyond the tip of the fibula. Again, take care to maintain a cuff of peroneal retinaculum and synovial sheath to function as a distal pulley.

When performing a stabilization procedure, if soft-tissue techniques fail to provide adequate stability, do not hesitate to perform a sliding osteotomy of the fibula or a reconstruction using a lateral slip of the Achilles tendon.

CONCLUSIONS

Early accurate diagnosis of PT pathology requires a high degree of suspicion. When it is detected, concomitant injury must be identified and treated in order to maximize the functional outcome. Individualize surgical treatment and address each identifiable pathologic condition.
FREIBERG'S INFRACTION

PATHOPHYSIOLOGY

Freiberg's infraction, caused by avascular necrosis of the epiphysis of the metatarsal head, was first reported in six cases in 1914. It occurs in adolescence, mostly affecting girls. The etiology is assumed to be traumatic insult causing loss of vascularity. It usually involves the second metatarsal, and less frequently the third and fourth. The second metatarsal head is affected because it is the longest ray and is the least mobile, as it is the keystone of the transverse arch of the foot.

Pain with weight bearing is the most frequent symptom. There can be associated swelling and loss of motion. The pain diminishes with rest and increases with activity. Physical examination shows swelling, tenderness, and discomfort with movement of the joint. If the osteophytes are large, they may be palpated.

Radiographic changes include sclerosis followed by loss of joint space and collapse of the metatarsal head in the late stage. There can be new bone formed as the metatarsal attempts to heal. Smillie's classification is based on the anteroposterior and oblique radiographs. In stage I, there is a fissure fracture of the ischemic epiphysis; in stage II, there is central depression of the head from bone resorption; in stage III, there is further collapse of the head with residual projections of the sides, and the plantar cartilage remains intact; in stage IV, the plantar portion of articular cartilage separates into a loose body; and stage V is the final stage, with arthritis, deformity, and flattening of the metatarsal head (Fig. 119.1).

Figure 119.1. Radiograph showing the typical appearance of Freiberg's infraction, with a large metatarsal head, flattening, and osteophytes.

If the disease is suspected but the radiographs are negative, a bone scan will show increased uptake in the early stage.

NONOPERATIVE TREATMENT

Most cases can be treated nonoperatively despite the radiographic appearance. In the early stages, cast immobilization for 4–6 weeks with protected weight bearing will decrease pain and swelling. Later, pressure under the affected metatarsal head can be reduced by a metatarsal pad, metatarsal bar, or a custom-molded orthosis. The disease is self-limited, and once the healing process begins, symptoms generally reduce. Sometimes the symptoms are present after complete healing. There can be residual pain and loss of motion from the bony prominence from the healed metatarsal head or the presence of loose bodies. In these cases, surgery may be indicated.

SURGICAL TREATMENT

Many surgical procedures have been described for treatment of symptomatic Freiberg's infraction. These include debridement, cheilectomy, osteotomy, resection arthroplasty, and metatarsophalangeal joint implant. If the articular cartilage is intact, debridement of the joint may be helpful to remove the synovitis, loose bodies, and osteophytes. Excision of excess bone is indicated if
the bony prominence is symptomatic.

- Make a dorsal hockey-stick incision over the second metatarsophalangeal joint, and incise the extensor tendons longitudinally to expose the joint.
- Perform a modified DuVries condylectomy (see Chapter 113).
- Perform a synovectomy, and remove the excess bone of the metatarsal head.
- Remove the dorsal one fourth to one third of the metatarsal head with an osteotome, and use a rongeur to excise any remaining sharp edges.
- Remove the medial and lateral osteophytes to the level of the metatarsal diaphysis. Extend the second toe to 75° to 80° to confirm that enough bone has been removed.
- Repair the extensor mechanism and the skin, and apply a firm compression dressing.

In cases that do not have remaining articular cartilage, consider resection of the metatarsal head. This procedure is not generally recommended because it will result in shortening of the toe, possibly transferring pain to the third metatarsal head.

**POSTOPERATIVE CARE**

Permit the patient to bear weight in a postoperative shoe. Remove the skin sutures at 2 weeks, and start the patient on passive and active range-of-motion exercises. An ordinary store-bought shoe may be worn once swelling has decreased. A metatarsal pad may be helpful during the first few weeks after resection to decrease the pressure under the metatarsal heads.

**PITFALLS AND COMPLICATIONS**

The patient's expectations should be fully investigated prior to the operative procedure and realistic expectations established. The most common postoperative complaint is continuation of some of the preoperative symptoms of pain and stiffness. Because the metatarsal head is involved, it is likely that some pain and stiffness will persist that may require shoewear modifications or possibly a secondary procedure.

Shortening of the toe and subluxation or dislocation are other possible complications. These may be prevented by limiting the amount of resection, and by limiting motion of the toe for 3 weeks with a K-wire, depending on the amount of dissection and excision. After pin removal, tape the toe for 3 weeks, and have the patient continue to wear the postoperative shoe.

Avoid excessive resection because of the possibility of transferring pressure to the third metatarsal head or even developing an intractable plantar keratosis.

**KÖHLER'S DISEASE**

**PATHOPHYSIOLOGY**

Köhler's disease is an osteochondrosis affecting the pediatric population. It is more commonly seen in male patients, and the average age of onset is 5–6 years, during the time of ossification of the navicular (11). The exact etiology of this disease is unknown, but it may be traumatic.

Pain, swelling, the inability to bear weight, and limping are the most common symptoms. There may be swelling and tenderness of the medial midfoot, and discomfort with ranging the transverse tarsal joints.

Radiographs show a flattened, dense, sclerotic navicular with some fragmentation (Fig. 119.2). Despite the collapse, the space for the navicular remains the same, which may account for the lack of residual deformity (Fig. 119.3). Only the ossification center is affected. Because there are few, if any, surgical pathologic specimens, the true etiology remains unknown.

**Figure 119.2.** Radiographs (A,B) of a patient with unilateral Köhler's disease show that the navicular on the affected side is flattened and sclerotic.

**Figure 119.3.** Lateral radiograph of a patient with Köhler's disease showing preservation of the space for the navicular despite fragmentation and flattening of the bone.

**TREATMENT**

The treatment of Köhler's disease is nonoperative and aimed at reducing symptoms. An arch support may be used, but cast immobilization for 6–8 weeks is more effective (11), especially when used initially with crutches. Follow-up radiographs are not necessary as these lesions heal, and by 6–13 months after onset the navicular has normal appearance and there are no known residual symptoms in adults.

**FLEXIBLE PES PLANUS**

**PATHOPHYSIOLOGY**

Flexible pes planus, also known as flexible flatfoot, is very common. Frequently seen in children, it is caused by ligamentous laxity and is considered a variation of normal (22). The medial longitudinal arch is determined by age and inheritable traits; it develops with age as the ligamentous laxity resolves and the subcutaneous fat decreases (23). Gould et al. (6) followed 125 toddlers from 11–14 months of age until 5 years of age. Initially, all the toddlers had pes planus, and arch development
occurred regardless of the type of footwear worn.

In a patient with flexible pes planus, the medial longitudinal arch is lost with weight bearing, but it reconstitutes with non-weight-bearing. Generally, a flexible flatfoot does not cause pain or disability. Even into adulthood, most patients do not develop pain or stiffness or require treatment. A flexible flatfoot can be associated with disability if there is an associated equinovarus contracture.

Symptomatic patients often complain of pain of the medial arch. Their arch can "feel tired." They may complain of difficulty in finding comfortable shoes, or they experience abnormal or excessive shoe wear. Inspect both lower extremities undressed to check foot posture and function during gait, standing, and sitting. Assess motion of the foot and ankle, and look for abnormal bony prominences. Look for an Achilles tendon contracture by inverting the subtalar joint and forefoot to lock the calcaneus under the talus while dorsiflexing the ankle.

Weight-bearing radiographs show talonavicular sag on the lateral view. Also, the angle between the longitudinal axis of the talus and the first metatarsal is increased; 0° is normal, 0° to 15° is a mild deformity, 15° to 30° is moderate, and more than 30° is severe. The anteroposterior view may reveal abduction of the talonavicular joint, leaving the medial portion of the talar head uncovered.

**CONSERVATIVE TREATMENT**

In the past, multiple treatment modalities have been tried for flatfoot deformity, but the current recommended treatment is observation in the asymptomatic child. The natural history of flexible pes planus is not changed by corrective shoes, orthotic devices, or exercises. Also, compliance was found to diminish with prolonged use of corrective shoe wear (over 3 years) (23).

In the occasional case where the parents see a functional improvement in a treated symptomatic patient, a supportive medial arch may be used. If the Achilles tendon is tight, initiate heel cord stretching exercises. Occasionally, sequential casting is needed to treat a tight heel cord. Place the talonavicular joint in the corrected position by placing the forefoot in varus (correct the lateral subluxation), and apply the cast with the ankle in neutral. Allow the patient to bear weight. Change the cast 2–3 weeks later; usually three casts changes are required for correction (4).

**SURGICAL TREATMENT**

Despite the large number of procedures performed for pes planus in the past, it is unusual that a surgical procedure is indicated. The operative options are a soft-tissue procedure, osteotomy, and fusion (4). If the disability is caused by an associated equinovarus contracture that does not respond to nonoperative measures, then a tendon Achilles lengthening is performed.

**Tendo Achilles Lengthening**

- Perform tendon Achilles lengthening through three small incisions along the length of the tendon, two medial and one lateral. Expose the tendon at each incision and then cut from the midline of the tendon outward.
- Repair the tendon sheath to help prevent scarring of the tendon to the skin.
- Extend the knee, and bring the foot up to 10° to 15° of dorsiflexion, taking care not to overlengthen the tendon.
- Repair the skin and place the limb in a short-leg cast with the ankle in neutral.

In some patients, pain may be caused by the development of stiffness from adaptive changes of soft-tissue or bone. The symptoms can be from severe pronation and heel valgus. In the past, a triple arthrodesis yielded the most reliable results. Currently, other procedures can alleviate the symptoms without the dramatic loss of motion by sparing the joints. These are osteotomies aimed at correcting the hyperpronation.

**Evans Procedure**

The Evans procedure involves lengthening the lateral column by placing a bone graft from the tibia into the anterior process of the calcaneus. It was described by Evans (2) as treatment of calcaneovalgus feet, in which the medial and lateral columns are equalized in length. This procedure preserves the calcaneocuboid joint and pushes the navicular bone medially in relation to the talus. The procedure has been popularized by Mosca (15).

- Perform the Evans procedure through a longitudinal incision over the lateral calcaneus, just superior and parallel to the peroneal tendons, and protecting the sural nerve. Expose the anterior calcaneus and calcaneocuboid joint (Fig. 119.4).

**Figure 119.4.** The Evans procedure.

- Do a vertical osteotomy of the anterior end of the calcaneus, anterior to the peroneal tubercle and parallel to the calcaneocuboid joint, and about 1.5 cm away from the joint between the anterior and middle facets.
- Take a cortical bone graft from the tibia, a bicortical iliac crest graft, or a piece of cortical allograft measuring approximately 1 cm, depending on the desired amount of correction. Place it between the osteotomized fragments so that the hindfoot valgus deformity is corrected.
- Use 2 mm Kirschner (K) wires for fixation.

Evans reported the results of this procedure in 56 feet in 1975 (2). The procedure was successful in treating calcaneovalgus caused by polio, painful rigid flatfoot, and idiopathic calcaneovalgus. It slightly improved the shape of the foot and relieved pain in patients with rigid flatfoot.

**Medial Displacement Osteotomy**

Alternatively, a medial displacement calcaneal osteotomy can be used to correct the deformity. The effect is to move the proximal calcaneus medially, which improves the excessive valgus, elevates the medial arch, and centralizes the motion of the subtalar joint (17).

- Make a lateral oblique incision over the lateral calcaneus above the peroneal tendons. Retract the tendons posteriorly and inferiorly with the sural nerve (Fig. 119.5).
Figure 119.5. Medial displacement osteotomy.

- Cut the calcaneus perpendicular to the body between the posterior facet and the posterior tuberosity.
- Perform the osteotomy with a saw; complete it with an osteotome at the medial cortex. Then bluntly strip the medial periosteum of the calcaneus.
- Open the osteotomy site with a lamina spreader, and then displace the proximal portion medially, one half of the width of the calcaneus, and tilt it to correct the valgus.
- Insert a bone graft to fill the gap and use two 2 mm K-wires (for a cannulated 7.3 mm screw), which are drilled from posterior to anterior, for fixation.

POSTOPERATIVE CARE

After a tendo Achillis lengthening procedure, apply a short-leg walking cast in the neutral position and begin weight bearing as tolerated for a total of 6 weeks.

For osteotomies of the calcaneus, initially apply a bulky compression dressing and splints. Remove the sutures at 2 weeks, and apply a non-weight-bearing cast for an additional 4 weeks. Allow weight bearing in a walking cast at 4–6 weeks after surgery. Remove the K-wires as an outpatient surgical procedure 8 weeks after surgery. Once the osteotomy has healed and the cast is removed, progress weight bearing with limitations on athletics. At 6 months, allow full activity.

PITFALLS AND COMPLICATIONS

Do not overlengthen a tight Achilles tendon. This procedure is rarely indicated in an adult because no growth potential remains. The presence of a fixed deformity in the hindfoot or midfoot or degenerative joint disease is a contraindication to a soft-tissue procedure or osteotomy. Perform arthrodeses for correction of deformity and alleviation of pain (see Chapter 115).

With a medial displacement osteotomy, take care at the medial aspect to strip but not cut the medial periosteum of the calcaneus, to avoid injury of the neurovascular structures and flexor tendons, which lie just on the periosteum.

RIGID PES PLANUS

PATHOPHYSIOLOGY

The etiology of rigid pes planus is different from that of a flexible deformity (Fig. 119.6). Usually, there is a bony abnormality, such as tarsal coalition, congenital vertical talus, or arthritis. Of these, tarsal coalition is the most common cause and can present as peroneal spastic flatfoot.

Figure 119.6. Lateral radiograph of an adult patient with rigid pes planus demonstrating adaptive bony changes. The patient also had a tight heel cord.

The cause of tarsal coalition is a failure of mesenchymal segmentation, and the resulting connection of two tarsal bones may be fibrous (syndesmosis), cartilaginous (synchondrosis), or bony (synostosis) (10). Tarsal coalition was described as long ago as 1769 by Buffon and can involve any combination of the tarsal bones (5). The tarsal coalition is an inherited disease that is autosomal dominant.

The incidence is 2%, with a calcaneonavicular bar being most common (10,18). The calcaneonavicular type becomes symptomatic when the coalition ossifies at 8–12 years of age. The talocalcaneal coalition frequently involves the medial facet, and it ossifies at 12–16 years of age. In a study of 22 patients with suspected coalitions, Herzenberg et al. found that 14 had a coalition documented by computed tomography (CT) scans, of which six were bilateral (6). All of the talocalcaneal coalitions involved the middle facet joint, and these were composed of bony or mixed osteocartilaginous tissue.

Most coalitions are asymptomatic or have mild symptoms. Tarsal coalition should be suspected in adolescents with painful and stiff pes planus. The most common age of presentation is the teen years, but patients can develop initial symptoms in their twenties to forties. Most patients complain of pain about the tarsal area, and stiffness and tightness of the peroneal and toe extensor muscles. They complain of difficulty with sports activities or even with standing and walking. Physical examination shows a rigid hindfoot, loss of the medial longitudinal arch, and fixed forefoot abduction. Spasm of the peroneal tendons can be seen by placing the foot into inversion: The result is contraction of the peroneus brevis or longus, or both.

Radiographs may show a naviculocalcaneal coalition on the oblique view of the foot (Fig. 119.7). The Harris view (posterior axial) can show a talocalcaneal coalition, but CT scans are more helpful in demonstrating this (Fig. 119.8). They are superior to plain tomography and radiographs for visualizing the three subtalar facet joints, as well as the size, nature, and location of the coalition. To obtain coronal cuts of the subtalar joint, position the patient supine with the hips and knees flexed, and place the feet in maximum plantar flexion and flat on the table so that the subtalar joint is perpendicular to the x-ray beam.

Figure 119.7. Oblique radiograph showing a complete bony coalition between the navicular and calcaneus.
NONOPERATIVE TREATMENT

Only those patients with symptoms require treatment. Rest, nonsteroidal anti-inflammatory medication, and cast immobilization will be helpful to some patients. Use a cast for at least 3 weeks; usually 6–8 weeks are required for relief of symptoms. Later, a shoe modification, such as a heel cup, a medial arch support, or a medial heel wedge, may allow patients to return to weight-bearing activities.

In a report of 14 patients (23 feet) with symptomatic talocalcaneal coalition, Scranton (19) found that five feet in three patients became asymptomatic after immobilization in a cast.

SURGICAL TREATMENT

Resection of tarsal coalition is the treatment of choice in a child with a middle facet coalition or a posterior facet coalition that comprises less than 25% of the joint surface and that is symptomatic and unresponsive to nonoperative treatment. Once symptomatic, the majority of patients do not respond to nonoperative treatment. Contraindications to coalition resection include degenerative arthritis, associated deformity, and involvement of greater than 50% of the posterior facet.

Excision of a Calcaneonavicular Coalition

- Make a lateral longitudinal or oblique incision over the sinus tarsi. Make full-thickness skin flaps, and identify and protect the sural nerve and peroneal tendons.
- Elevate the extensor digitorum brevis from its origin from proximal to distal to expose the coalition.
- Excise the coalition with an osteotome, ronguer, or motorized burr.
- Once the bar is completely removed, transfer the extensor digitorum brevis muscle into the defect of the excised coalition, holding it there with absorbable sutures. A convenient method is to use a pullout suture.
- Close the skin incision and apply a bulky dressing and well-padded splints.

Excision of a Talocalcaneal Coalition

- Make a medial longitudinal curvilinear incision 6 cm long, just plantar to the posterior tibial tendon.
- Develop the interval between the flexor digitorum longus and the flexor hallucis longus tendons, retracting the neurovascular bundle plantarward.
- Localize the coalition with two Keith needles on either side using fluoroscopy. Then excise about 5–7 mm of the bar with an osteotome or motorized burr until motion in the subtalar joint is restored.
- Apply bone wax to the cut bony surfaces to control bleeding. Then interpose fat harvested from the posterior aspect of the calcaneus into the gap.
- Repair the flexor digitorum and hallucis longus tendon sheaths, and then close the skin. Apply a bulky dressing and short-leg splints.

In adults, excision of the coalition is generally not recommended, although this is controversial. Excision alone is definitely contraindicated if degenerative changes are present. Note that talar beaking is a traction spur on the dorsum of the talus and not degenerative arthritis. In young adults with no or minimal degenerative changes or deformity, an excision may be attempted to delay fusion. Some authors advocate this treatment initially.Scranton (19) reported that of 14 feet that underwent resection of a talocalcaneal coalition, 13 had a good result and 1 a satisfactory result. No patient had a poor result. He found that once the coalition was excised, the anterior and posterior facet joints appeared normal. Olney and Asher (16) had satisfactory results in 8 of 10 feet after resection of talocalcaneal coalition, and all patients appeared to have increased in the range of motion in the subtalar joint.

A fusion yields the most reliable result. If the deformity can be corrected by fusing the subtalar joint, the transverse tarsal joints can be spared. This is my preferred method of surgical treatment if there are no degenerative changes of the talonavicular and calcaneocuboid joints. In the patient with severe deformity and disabling pain, a triple arthrodesis is the procedure of choice. If there is an associated equinus contracture, a tendon Achilles lengthening may be needed to fully correct the deformity.

POSTOPERATIVE CARE

Remove the sutures about 2 weeks after coalition excision surgery, and begin range-of-motion exercises. Continue non-weight-bearing until ranging the subtalar joint does not cause pain, which is usually about 6 weeks. At that time, begin weight bearing.

Protect a subtalar or triple arthrodesis with a bulky compression dressing and splints in the first 2 weeks, and then remove the staples or sutures. Apply a non-weight-bearing cast, which is worn for 4 weeks, followed by a walking cast for the next 6 weeks until bony union occurs. After this, a well-cushioned wide shoe may be worn.

PITFALLS AND COMPLICATIONS

Inadequate resection may cause impingement or continued limitation of motion. Gonzalez and Kumar (5) reported in 75 feet that only 22% had partial reformation of the coalition. In no patient did the coalition reform completely.

Older patients should be informed that their pain may persist, especially if there are degenerative changes. If excision is the initial treatment, a fusion later may be required. Talar beaking, however, is not a contraindication to resection of the coalition alone, and it may be resected at the time of surgery if symptomatic. Patients who have good to excellent early results continue to do well even at 10 years follow-up (7).

ACCESSORY NAVICULAR

PATHOPHYSIOLOGY

The accessory navicular is an accessory bone that is also called the accessory scaphoid, prehallux, os tibiale, os tibiale externum, naviculare secundarium, and navicular secundum. It was initially described by Bauhin in 1605 (7). The accessory navicular sits posterior medial to the navicular (Fig. 119.9), and it ossifies between 9 and 11 years of age. It is seen radiographically with much variation, small to large, round to triangular. Its connection to the navicular may be fibrous, cartilaginous, or bony.
There are three types of accessory navicular, as determined by radiographic appearance. Type I is an ossicle that lies within the posterior tibial tendon, type II is connected to the navicular by a cartilaginous bridge, and type III is a cornuate-shaped navicular from fusion of the accessory bone to the navicular. Accessory navicular is quite common—2% to 14% of the population and is bilateral in 77% to 100% of cases (7,8).

There is some controversy as to whether the accessory navicular can cause pes planus. Generally, the patient has a flatfoot deformity and the accessory bone interferes with the normal mechanics of the posterior tibial tendon. Kidner (12,13) believed that removal of the accessory navicular would allow a straighter pull of the tendon and thus improvement of the flatfoot deformity.

Most cases of accessory navicular are asymptomatic, and less than 1% require surgical treatment (1). The source symptoms in an accessory navicular are not absolutely clear. Inflammation of the surrounding soft tissues from the prominence or trauma to the cartilaginous bridge may cause pain. Repetitive stresses on a cartilage bridge may result in a painful stress fracture (7).

Symptoms usually begin in the teen years, as pain in the mid-medial arch aggravated by weight bearing. In adults, initial symptoms may appear after a severe twisting injury, often occurring in sports.

Physical examination will reveal a bony prominence of the proximal medial border of the navicular with tenderness over the accessory bone. There can be associated local edema and erythema.

The accessory bone is usually visible on plain radiographs of the foot. A bone scan may help to localize and differentiate the pathologic cause of medial arch pain, but it is rarely necessary.

**NONOPERATIVE TREATMENT**

Nonoperative treatment is generally effective and consists of rest from activity, nonsteroidal anti-inflammatory medication, and shoewear modification. A wider shoe will relieve the pressure over the bony prominence. With a flatfoot deformity, a medial arch in a custom orthotic device may reduce the stress on the medial longitudinal arch.

Acute symptoms associated with an injury, even a minor sprain, can be treated with a short course of cast immobilization for 3–6 weeks. After casting, usual activities can be resumed as symptoms allow.

**SURGICAL TREATMENT**

In cases of disabling pain that is unresponsive to nonoperative treatment, excision of the accessory bone is indicated. Excision of the accessory bone with advancement of the posterior tibial tendon is known as the Kidner procedure. However, there is little advantage to advancing the tendon, and I do not recommend it.

- Make a 3–4 cm medial longitudinal incision over the insertion of the posterior tibial tendon, incise the tendon longitudinally, and visualize the accessory navicular.
- Excise the accessory navicular. The remaining navicular tuberosity is usually prominent, so use a ronguer to create a smooth surface. Apply bone wax to the cut surface to decrease postoperative bleeding.
- Repair the posterior tibial tendon with interrupted absorbable sutures. If the defect is large, repair the tendon and advance it through a drill hole in the navicular; bring it out the dorsum and suture it onto itself.

**POSTOPERATIVE CARE**

Immobilize the foot in some plantar flexion and minimal inversion in a bulky compressive dressing with splints. Remove the sutures at 2 weeks, and place the foot in the same position in a fiberglass cast until 3 weeks. Continue immobilization in a removable cast for an additional 3 weeks, and then begin weight bearing as tolerated.

Begin range-of-motion and strengthening exercises after removal of the cast, and prescribe a custom orthotic device with a molded arch if necessary.

**PITFALLS AND COMPLICATIONS**

If some prominence of the navicular remains, symptoms of pressure against shoewear may persist. Sometimes tenderness persists over the medial eminence area, especially in adults. To prevent this problem, remove sufficient bone and smooth the remaining surface with a ronguer.

If the patient has another anatomic abnormality, including symptomatic flatfoot, equinus contracture, or a tarsal coalition, the treatment must address these problems as well.

Chapter References

The number of lower extremity amputations performed in the United States annually has remained fairly steadily between 30,000 and 40,000 over the last 15 years (3). Most of the amputees are older people with ischemic disease of the lower extremities or diabetes of long standing. Amputations are a major social and economic burden to society. Moreover, the amputation of one lower extremity in the elderly at too frequently is followed by the amputation of the contralateral limb; this occurs in 15% to 28% of cases within 3 years. Only 50% of elderly amputees survive the first 3 years following an amputation. In spite of the advances in medicine these statistics have not improved significantly for the dysvascular amputee (9,12,14,58,63).

An amputation, however, does not have to be considered a failure of treatment. Frequently, it is the treatment of choice for a devastating injury to the lower extremity where reconstruction may be a long and costly undertaking that leads to the preservation of a functionally unsatisfactory extremity (33,34 and 38,65,72). It is important that amputation be done well and with adequate preoperative planning (4), so that the outcome results in a residual limb that can wear a prosthesis comfortably. With a prosthesis that fits well, the patient is most likely to become an active member of society and independent in his life-style.

Because of the complexity of the conditions that can lead to an amputation, a treatment team is required that includes the primary care physicians, the surgeons, a physical therapist, a prosthetist, and a social worker (53). The patient must be involved and committed to a successful outcome. In the case of patients with vascular disease, other organ systems are usually involved. An internist who is familiar with the patient’s condition must be involved and should counsel the patient (5,13,52).

PERIPHERAL VASCULAR DISEASE

Vascular insufficiency is the most common problem requiring amputation and usually occurs in the geriatric patient. Since preservation of a functioning knee greatly improves the chances of rehabilitation of the amputee, consider reconstruction of occluded major proximal arteries, which may save the limb or at least allow amputation below the knee (1,25,58,67,71,72).

The largest subset of patients with peripheral vascular disease are those with diabetes mellitus (27,48,61). These patients have the added problems of peripheral neuropathy. Therefore, they are subject to trophic ulcers and Charcot osteoarthropathy. Indeed, frequently the amputation in patients with diabetes is performed because of osteomyelitis caused by a trophic ulcer that has exposed bones of the foot. Instability of the foot or ankle because of the osteoarthropathy may also require amputation (8,44,63).

TRAUMA

When a patient requires an amputation for trauma, it is usually because of an irreparable acute vascular injury. Treatment of lacerations of the popliteal artery has improved: During World War II, amputation occurred in 72% of these cases (15), whereas 68% were successfully treated with vascular reconstruction in both the Korean War (39) and the Vietnam War. This rate of success has been reflected in the civilian experience (13,15,39,66).

Limb salvage in the severely injured lower extremity with an open fracture, a vascular injury requiring repair, or transection of the posterior tibial nerve is challenging, requiring a long and expensive course of treatment with numerous surgical procedures. Even if the limb can be saved, it is often painful and not as useful as a prosthesis. This, together with a protracted course of treatment, places an undue psychological burden on the patient (38,40,63). See Chapter 12 and Chapter 24 for a thorough discussion of these issues.

MALIGNANCIES

The development of limb salvage procedures for malignant tumors of the extremities, combined with adjuvant therapy, has reduced the incidence of amputations for primary malignancies of the lower extremities (19,20,41,50,57,70,75). This is discussed in detail in Chapter 128 and Chapter 129.

LEVELS OF AMPUTATION

The optimal stump is covered with durable, wellvascularized subcutaneous tissue and skin that will withstand pressure in weight-bearing areas, and friction in areas covered by the prosthesis. Stumps that allow end bearing are particularly desirable. Usually, end-bearing stumps retain a part of the sole pad or have a bony surface of sufficient size that it can bear the body weight for varying periods of time. These conditions are common in partial foot amputations.

Another means of creating an end-bearing stump is ankle or knee disarticulation. Disarticulation is particularly desirable in growing children and in the elderly. In children, overgrowth, which is seen often in diaphyseal amputations, is avoided by retaining the epiphysis (26,45). In the elderly, an end-bearing stump decreases problems with fitting and improves the chances for rehabilitation (37,64). The creation of a tibiofibular synostosis as described by Ertl (24) can create end-bearing conditions somewhat comparable to those of the disarticulation.
Because a well-vascularized and durable skin is so important for the healing of the amputation wound, several methods have been developed to predict at which level of the lower extremity the circulation in the skin is adequate for primary wound healing. One of these is the xenon-133 (133Xe) clearance. After the ambient conditions have been regulated, radionuclide is injected intradermally. A gamma camera monitors the 133Xe activity for 10 minutes. The faster the 133Xe is cleared from the site of injection, the better the perfusion of the skin (34-48).

Of the noninvasive methods of predicting success in major amputations, the most accurate is probably the transcutaneous measurement of oxygen tension. The oxygen sensor is calibrated for temperature and atmospheric pressure and applied to the skin. The skin is heated to 45°C. The sensor stabilizes after approximately 20 minutes. The minimal desirable tension varies between 30 and 50 mm of mercury (7,47).

However, none of the methods for measuring blood flow in the affected extremity is entirely reliable for predicting success in healing of the amputation wound. Other conditions, such as nutrition, state of health, age, collateral circulation, and infection, play a role in the success or failure of the amputation.

The various levels of amputation are depicted in Figure 120.1. See Chapter 175 for amputations in children.

**TISSUE MANAGEMENT**

The skin is the most important tissue for the healing of the amputation wound. It is therefore important that it be handled with care. The use of skin hooks in particular is desirable in patients with dysvascular extremities.

Skin grafting, although for a long time frowned upon, is not entirely contraindicated in the lower extremity. As long as a split-thickness graft is over soft tissue and not adherent to bone or thick scars, it is likely to withstand the prosthetic wear. Pedicle grafts do even better as long as they are not in the immediate weight-bearing area of the residual extremity (74). Skin grafts are more successful in children than in adults.

The transected muscles should provide an adequate soft-tissue mantle for the residual extremity. This can be achieved best through myodesis (sutting the transected muscle end to drill holes in the bone) or myoplasty (sutting the cut ends of the antagonist muscle groups and their fascias together). Under normal circumstances, the cut muscle ends have the greatest amount of capillary bleeding. Therefore, the suction drain should be in this layer of the amputation stump.

Where bones cannot be used for actual weight-bearing stumps, such as in partial foot amputations or disarticulations, bony prominence under this skin should be removed. Consider the possibility of an osteoplastic treatment of the bones, such as a tibiofibular synostosis (24).

Transsection of the nerves during amputation leads without exception to the formation of neuromas. In the vast majority, these neuromas are painless. However, where the cut end of the nerve is within the weight-bearing area of the residual extremity, the neuroma can become painful. Therefore, during the amputation each nerve should be identified, dissected free to a level well above the amputation, and sharply transected. Where a concomitant vessel is expected, ligate the nerve before cutting it under minimal tension.

Dissect the larger veins and arteries free and doubly ligate them before transection. It is advisable not to catch neighboring veins and arteries in the same ligature, since this might lead to the development of aneurysms.

**SURGICAL TECHNIQUES**

**OPEN AMPUTATION**

When amputation becomes necessary in patients with overwhelming infections, particularly infection by gas-producing bacteria, an open amputation (43,66,69) may be indicated. The aim of this surgery is to eradicate the diseased area without creating a harbor for renewed infection. Although a straight guillotine transverse amputation is the simplest, we prefer to develop flaps as the secondary revision, and closure is then usually easier.

- Prepare the skin flaps that are necessary for the secondary closure of the amputation wound. You may want to make the initial skin flaps somewhat longer than usual, as some retraction will occur.
- Transect the soft tissues and bone in the usual fashion.
- Carry out hemostasis and transection of the nerves as described previously.
- To prevent the skin flaps from retracting, invert and suture the free skin edges to the subcutaneous fascia at the base of the flaps with nonabsorbable sutures to be unrolled at the time of secondary closure (Figure 120.2). Only in patients with excellent circulation should you use skin traction to prevent skin retraction.

**Figure 120.2.** Open amputation with preservation of flap length using inversion technique. See text for details. (From Bohne WHO. Atlas of Amputation Surgery. New York: Thieme Medical, 1987:36, Fig. 8-9, with permission.)
The procedure in both amputations is somewhat similar to that of the transmetatarsal amputation.

When one of these amputations is successful, its advantages are that it is end bearing, does not sacrifice leg length, and requires only a filler in a regular shoe in most cases.

Increased weight-bearing pressures over the plantar aspect of the end of the stump may lead to pain and/or ulceration. On the other hand, when one of these amputations fails, resection of the foot is indicated when there is a perforating ulcer under one of the metatarsal heads that has not healed in spite of prolonged care, and when osteomyelitis involves the metatarsal.

The LisFranc amputation is carried out through the tarsometatarsal joints, whereas the Chopart amputation is a disarticulation through the talonavicular and calcaneocuboid joints. Both amputations sacrifice the insertions of the muscles that aid in the extension of the ankle joint; therefore, the anterior tibial tendon, the toe extensors, and the peroneal tendons must be reinserted into the tarsal bones. Even so, dorsiflexion of the ankle joints often is inadequate, requiring a transmetatarsal Achilles tenotomy. These levels of amputations are less desirable than a transmetatarsal amputation, as the stump has a tendency to develop an equinus posture over time.

The advantage of transmetatarsal amputation is the possibility of eradicating the disease processes that involve the toes and the metatarsal heads and necks. It requires a long plantar flap to cover the anterior part of the amputation wound. In general, it creates an excellent weight-bearing foot remnant. However, you must consider that the fifth metatarsal is more horizontal than the first metatarsal, so the shoe insert that is required after the rehabilitation has to provide sufficient medial support to distribute weight bearing evenly.

This procedure requires transection of the dorsal skin slightly distal to the level of the bony amputation. The plantar flap must be long enough to cover the ensuing amputation wound. It must avoid any ulcerations that may be present on the plantar surface of the forefoot (Figure 120.4.D). Transect the flexor tendons and let them retract. Identify the neurovascular bundles. Cut the digital nerves back sharply and ligate the arteries and veins. Transect the extensor tendon and let it retract.

Skin closure. (From Bohne WHO. Atlas of Amputation Surgery. New York: Thieme Medical, 1987:40–42, Fig. 10-1, Fig. 10-2, Fig. 10-3, Fig. 10-4, Fig. 10-5 and Fig. 10-6 with permission.)

The Lis Franc amputation is carried out through the tarsometatarsal joints, whereas the Chopart amputation is a disarticulation through the talonavicular and calcaneocuboid joints. Both amputations sacrifice the insertions of the muscles that aid in the extension of the ankle joint; therefore, the anterior tibial tendon, the toe extensors, and the peroneal tendons must be reinserted into the tarsal bones. Even so, dorsiflexion of the ankle joints often is inadequate, requiring a transmetatarsal Achilles tenotomy. These levels of amputations are less desirable than a transmetatarsal amputation, as the stump has a tendency to develop an equinus posture over time. Increased weight-bearing pressures over the plantar aspect of the end of the stump may lead to pain and/or ulceration. On the other hand, when one of these amputations is successful, its advantages are that it is end bearing, does not sacrifice leg length, and requires only a filler in a regular shoe in most cases.

The procedure in both amputations is somewhat similar to that of the transmetatarsal amputation.

TRANSMETATARSAL AMPUTATION

The LisFranc amputation involves the metatarsal.

RAY RESECTION OF THE FOOT

Ray resection of the foot is indicated when there is a perforating ulcer under one of the metatarsal heads that has not healed in spite of prolonged care, and when osteomyelitis involves the metatarsal.

Achilles tenotomy. These levels of amputations are less desirable than a transmetatarsal amputation, as the stump has a tendency to develop an equinus posture over time. Increased weight-bearing pressures over the plantar aspect of the end of the stump may lead to pain and/or ulceration. On the other hand, when one of these amputations fails, resection of the foot is indicated when there is a perforating ulcer under one of the metatarsal heads that has not healed in spite of prolonged care, and when osteomyelitis involves the metatarsal.

The LisFranc amputation is carried out through the tarsometatarsal joints, whereas the Chopart amputation is a disarticulation through the talonavicular and calcaneocuboid joints. Both amputations sacrifice the insertions of the muscles that aid in the extension of the ankle joint; therefore, the anterior tibial tendon, the toe extensors, and the peroneal tendons must be reinserted into the tarsal bones.
care not to injure the medial or lateral plantar artery and nerves.

- Dissect the part of the foot to be amputated off the plantar flap, which should not be debrided to allow full-thickness coverage of the anterior part of the stump.
- Leave the cartilage of the tarsal bones and the remaining limb intact. This cartilage presents an effective barrier against infections of the bone, and it decreases blood loss from bone bleeding. Nevertheless, introduce a drain into the amputation wound.
- Close the plantar flap to the dorsal incision, securing the deep fascia to the periostium and deep fascia of the stump with absorbable sutures. Close the skin with interrupted 4-0 or 5-0 nylon or similar sutures.

The Chopart amputation is the highest level of amputation of the foot that allows the possibility of fitting with a shoe and shoe filler; however, frequently the patient prefers a formal prosthesis because the shoe is unstable (10).

**BOYD AMPUTATION**

The Boyd procedure provides a broad weight-bearing surface of the heel by creating an arthrodesis between the distal tibia and the tuber of the calcaneus (45). Compared to a Syme's amputation, it provides more length and better preserves the weight-bearing function of the heel pad. Its increased complexity and morbidity have made it less used now than the Syme's amputation. The Pirogoff amputation removes the anterior two thirds of the calcaneus (Figure 120.5) but has no advantage over the Boyd amputation, which is described later.

**Figure 120.5.** Pirogoff amputation with fixation of the tuberosity of the calcaneus to the tibia. (From Bohne WHO. Atlas of Amputation Surgery. New York: Thieme Medical, 1987:53, Fig. 12-7, with permission.)

- Make the dorsal skin incision from the medial to the lateral malleolus across the anterior aspect of the ankle joint. Connect this to a plantar incision through the plantar fat pad at the midtarsal joint region. Take care not to injure the tibial neurovascular bundle. Plantar-flex the foot. Place a bone hook in the posterior talus and pull it forward. Excise the talus. The plantar pad remains attached to the undersurface of the calcaneus. Remove the portion of the foot to be amputated (Figure 120.6 A).

**Figure 120.6.** Boyd amputation. See text for details. A: Anterior–dorsal skin incision and exposure with excision of the talus. B: Excise the anterior process of the calcaneus and remove cartilage from the articular facets. Fit the calcaneus into the ankle mortise, shifting it anteriorly. Secure it with a Steinmann pin. C: Completed amputation with skin closure. (From Bohne WHO. Atlas of Amputation Surgery. New York: Thieme Medical, 1987:56–57, Fig. 12-11, Fig. 12-13, Fig. 12-14, with permission.)

- Remove the anterior process of the calcaneus. Fashion the ankle mortise in such a way that the decorticated superior part of the tuber calcanei can be fitted into the ankle mortise with good bone apposition. Slide the calcaneus somewhat anteriorly.
- Fix the tuber calcanei into the ankle mortise with either a Steinmann pin or a partially threaded cancellous screw (Figure 120.6 B).
- Pull the plantar skin flap over the anterior aspect of the calcaneal remanent, and close it in layers at the anterior aspect of the ankle joint (Fig. 120.6 C). Postoperative casting may be necessary to provide secure arthrodesis between the ankle mortise and the calcaneal remanent.

**SYME’S AMPUTATION**

The Syme's amputation provides an end-bearing stump that in many circumstances allows amputation without a prosthesis over short distances. It is an excellent amputation for children, in whom it preserves the physes at the distal end of the tibia and fibula (28).

The Syme's amputation works well for tumors and trauma, assuming that the heel flap has been spared from the trauma. In the past, it has had a high failure rate in ischemic limbs because of failure of wound healing. Today, the success of amputation at this level has increased because local tissue perfusion is preoperatively determined with Doppler ultrasound measurement of blood pressures, with radioactive 133Xe clearance tests, and with transcutaneous measurement of oxygenation.

In infected limbs, particularly in diabetics, a two-stage amputation, where the wound is left open initially and the viability of the heel flap is established prior to definitive wound closure, has also increased success rates. The two most common problems with the Syme's amputation are skin slough due to trimming of the dog-ears of the skin flaps, which interferes with the blood supply to the heel pad, or late migration of the heel pad due to instability. The risk of both of these problems can be minimized by careful attention to surgical technique.

The only other objection to the Syme's amputation is that a below-knee prosthesis must be worn, which is rather bulky around the ankle because of the need to accommodate the flair of the distal tibial metaphysis. The prosthesis consists of a molded plastic socket with a removable medial window through which the stump is inserted. Usually a solid-ankle, cushion-heel (SACH) foot is attached. For this reason, the Syme's amputation has not often been recommended for women, but active athletic women probably would prefer this level of amputation because it is much more functional for sports activities than a standard below-knee amputation.

- Make a dorsal skin incision from the medial to the lateral malleolus over the anterior aspect of the ankle joint. Continue the plantar incision around the anterior process of the calcaneus (Figure 120.7 A). Transect the extensor tendons and cut back sharply the cutaneous nerves. Ligate the dorsalis pedis artery and vein.
Amputation of the ischemic limb in the sagittal plane. (From Bohne WHO. Atlas of Amputation Surgery. New York: Thieme Medical, 1987:58–62, Fig. 12-15, Fig. 12-21, Fig. 12-22 and Fig. 12-23, with permission.)

- Disarticulate the talus from the ankle mortise by transecting the medial and lateral collateral ligaments. Take care not to injure the tibial neurovascular bundle. Strip the calcaneus subperiosteally and remove it from the heel pad. This dissection can be difficult and is aided by placing a bone hook into the posterior aspect of the talus and pulling it and the calcaneus anteriorly. Then use a sharp scalpel to meticulously dissect the calcaneus free from the heel pad, at a subperiosteal level.
- When the calcaneus is free, transect the plantar tendons and neurovascular bundles, taking care to protect the vascular supply and sensory nerves to the heel pad.
- In a standard Syme's amputation in adults, remove the malleoli at the level shown in Figure 120.7.6. In children and for first-stage amputations in diabetics, leave the malleoli intact.
- Start closure of the wound by suturing the anterior tibial tendon as well as the extensor digitorum longus tendon into the anterior part of the heel pad. This prevents, at least to some extent, posterior migration of the heel pad (Figure 120.7.C). Complete a layered closure as described previously.
- Since the removal of the calcaneus from the heel pad creates a large empty space, insert a suction drain to prevent the formation of a large hematoma. There is a mismatch between the thin skin at the anterior aspect of the ankle joint and the thick plantar skin. However, the ridge that is created by the skin closure flattens out eventually. Large dog-ears are usually created by this closure. Do not trim these. They eventually flatten out.

BELOW-KNEE AMPUTATIONS

Select a site of amputation that is at a level where good soft-tissue coverage of the bony stump end is possible. The minimal length of the bony stump for good function is about 12 cm, as measured from the medial tibial plateau distally, and the maximum length is 17 cm, depending on the height of the patient. Longer stumps require less energy consumption during gait and can be fitted with sockets without special suspension. Very short stumps often require knee hinges and a thigh lacer and are much less functional.

There are three common approaches to developing skin flaps. The first provides equal skin flaps medially and laterally (2), the second provides equal skin flaps posteriorly and anteriorly; the third and most common approach provides a long posterior flap. The latter is most desirable in dysvascular patients and leaves the patient with a scar on the anterior aspect of the residual limb. However, other methods of skin closure have been successful (Figure 120.8) (32,42,68).

Figure 120.7. Syme's amputation. A: Skin incisions. B: Level of bone transection in adults. C: Begin closure of the wound by attaching the extensor tendons to the calcaneal periosteum to help stabilize the heel pad. D: Skin closure. (From Bohne WHO. Atlas of Amputation Surgery. New York: Thieme Medical, 1987:69, Fig. 12-1, Fig. 12-2, Fig. 12-3, Fig. 12-4 and Fig. 12-5, with permission.)

- Determine the level of transection of the tibia by direct measurement, or using the method depicted in Figure 120.9.

Figure 120.9. Use a sterile marking pen to divide the leg into four equal quadrants from the tibial plateau to the myotendinous junction of the gastrocnemius muscle. In most cases, transect the bone at the distal portion of the third quarter.

- In the long posterior flap method, make the skin incision at the anterior aspect of the tibia. 1.3 cm distal to the level of the bone transection. The posterior flap must be long enough to provide soft-tissue coverage without undue tension (Figure 120.10). Extend the incision down to the deep fascia and periosteum of the tibia veering medially and laterally to point B on Figure 120.10., which is two thirds of the anteroposterior (AP) diameter of the calf. Then curve the incision directly distal for a distance of 1.3 cm before sloping posteriorly to create the posterior flap. The length of the posterior flap must be more than two thirds of the AP diameter of the calf at the level of the bone transection.

Figure 120.10. Skin incision for a below-knee amputation as described by Mooney.

- Raise the periosteum of the tibia and transect it with an oscillating saw. Bevel the anterior aspect of the tibia. Transect the fibula with an oscillating saw 1–2 cm proximal to the level of the tibial transection.
- Working from anterior to posterior, transect the muscles and neurovascular bundles. Pulling the distal tibia anteriorly places the soft tissues under tension and facilitates dissection. Transect the muscles of the anterior, lateral, and deep posterior compartments just distal to the end of the tibia, so that when they retract they are even with the end of the tibia. Identify each neurovascular bundle. Cut the nerves back sharply and doubly ligate the arteries and veins independently.
- Bevel the posterior flap to produce adequate coverage for the end of the amputation stump. At the level of the skin, it should consist only of fascia.
- Carry out a myoplastic closure, suturing the fascia of the posterior flap to the anterior compartment and the periosteum of the tibia. Lead a drain out through the
skin laterally. Particularly in the dysvascular patient, avoid any tension in the skin closure (Figure 120.11).

Figure 120.11. Below-knee amputation. Myoplastic closure with approximation of the fascia of the posterior flap to the fascia of the anterior compartment and periosteum of the tibia, and subsequent closure of the subcutaneous tissues and skin over a drain placed at the level of the bone. (From Bohne WHO. Atlas of Amputation Surgery. New York: Thieme Medical, 1987:68, Fig. 13-7, with permission.)

KNEE DISARTICULATION

Amputation through the knee offers numerous advantages. The main advantage is the creation of an endbearing stump and preservation of the distal femoral physes, which is particularly desirable in children. Another advantage is the maintenance of a long active lever arm for control of the prosthesis, with excellent muscle attachments. The bulbous distal stump enhances suspension of the prosthesis. In elderly dysvascular patients, the longer stump helps prevent hip flexion contractures and provides better balance for wheelchair activities. Knee disarticulation is most useful in young athletic amputees in whom a below-knee amputation is not feasible. Several modifications have been introduced by Mazet and Hennessy (60) and Burgess (6), and they are incorporated here.

- Equal anteroposterior or mediolateral skin flaps using a fishmouth type of incision are acceptable.
- Start the anterior skin incision approximately 2 cm below the tibial tubercle. The posterior incision is usually at the level of the distal popliteal flexion crease.
- Raise a skin and subcutaneous fat flap and transect the patellar ligament as far distally as possible.
- Open the anterior capsule and transect the collateral ligaments. Transect the cruciate ligaments at their insertion on the tibial plateau.
- Open the posterior capsule and doubly ligate the popliteal vessels distally to the level of the superior geniculate artery. Sharply transect the nerves well proximally to the skin incision.
- Transect the tendons of the knee flexors as far distally as possible.
- Using an oscillating saw, remove the femoral condyles 1.5 cm proximal to the knee joint.
- Shell the patella out of the patellar tendon. Suture the patellar tendon and the flexor tendons of the knee to the cruciate ligaments (Fig. 120.12).

Figure 120.12. Knee disarticulation. Suturing of the patellar ligament to the cruciate ligaments. Suturing of the hamstring tendons to the cruciate ligaments and resection of the distal femoral condyles as described by Burgess (6) is not illustrated.

- Although there is very little bleeding after this procedure, insert a drain into the wound. Complete the procedure with subcutaneous and skin sutures.

ABOVE-KNEE AMPUTATION

Whenever preservation of the knee joint is impossible, diaphyseal amputation through the femur becomes necessary. The soft-tissue coverage of the above-knee stump is excellent and usually provides good arterial perfusion to allow primary healing of the amputation. It is the most commonly used amputation for vascular disease because it heals reliably. The optional level for prosthetic fitting is at the junction of the distal and middle thirds.

Although patients with a stump length of 10 cm below the gluteal crease have been fitted successfully with prostheses, a longer amputation stump makes prosthetic fitting, as well as rehabilitation, easier and more successful. Equal anterior and posterior soft-tissue flaps are used most commonly, but atypical soft-tissue coverage is well tolerated in above-knee amputations.

- Make a fishmouth skin incision to create equal anterior and posterior flaps (Figure 120.13.A).

Figure 120.13. Above-knee transdiaphyseal amputation. A: Skin incisions relative to the level of transection of the femur. B: Myodesis closure of the stump over a drain. (From Bohne WHO. Atlas of Amputation Surgery. New York: Thieme Medical, 1987:87–89, Fig. 14-4, 14-7, with permission.)

- After the skin incision, transect the quadriceps musculature anteriorly; this will leave the muscle even with the level of bone transection.
- Next, either cut the femur (as this permits the transection of tissues from anterior to posterior) or complete the soft-tissue work prior to cutting the bone. Cut the adductors and hamstrings so that they also lie even with the cut bone.
- If you have not done so already, transect the bone and round off the sharp edges.
- Obtain hemostasis and isolate and doubly ligate the large vessels with at least one suture ligature. Place a ligature on the sciatic nerve well above the level of amputation, prior to sharply transecting the nerve.
- Fashion the muscle flaps and do a myoplasty by approximating the anterior to the posterior myofascial flap (Figure 120.13.B). In younger active patients, place two drill holes in the bony stump end for each compartment, and do a myodesis by pulling the muscles out to length and securing them to the bone end with sutures. This improves the power and control over the stump and keeps the bone centralized in the stump.
- Place a drain and close the subcutaneous flap and skin loosely with interrupted sutures or staples.

HIP DISARTICULATION
Hip disarticulation is done today mainly to eradicate malignancies. Prosthetic fitting is quite possible, although rehabilitation is most successful in younger and more vigorous individuals, since the prosthetic gait requires considerable expenditure of energy. Very short above-knee amputations (Figure 120.1) are fitted with a hip disarticulation prosthesis (Chapter 122), as is the short stump that cannot control an above-knee prosthesis even with a hip hinge and waist belt.

- Place the patient in the lateral decubitus position with the operated side uppermost, and prepare and drape the limb free, including the hip and groin.
- Make a racket-type incision down to the deep fascia, that starts at the anterior superior iliac spine, follows the inguinal ligament to a point 5 cm below the public tubercle, and curves around the medial and postcrclateral aspects of the thigh approximately 5 cm below the ischiatic tuberosity. The incision then extends anteriorly to the greater trochanter and joins the beginning of the incision at the anterior iliac spine (Figure 120.14.A).

**Figure 120.14.** Disarticulation of the hip. See text for details. A: Racket-type skin incision. B: The hip disarticulation is completed except for cutting the ligamentum teres. C: Skin closure. D: Frontal view of a patient after hip disarticulation. (From Bohne WHO. Atlas of Amputation Surgery. New York: Thieme Medical, 1987:106–111, Fig. 14-28, Fig. 14-31, Fig. 14-34, Fig. 14-35, with permission.)

- Anteriorly expose the femoral artery and vein. Isolate them and doubly ligate them. Dissect the femoral nerve free, ligate it, and transect it sharply farther proximally.
- Transect the muscles originating from the iliac spine and retract them distally. Transect the pectineus muscle a finger's breadth laterally to the pubic ramus. Externally rotate the hip and transect the psos tendon. Next, detach the muscles from the pubic bone and the adductor magnus as it originates from the ischium.
- Between pectineus and the hip external rotators, dissect the obturator artery free and ligate it. Transect the obturator externus distal to the obturator foramen, because inadvertent transection of the obturator artery leads to retraction of the vessel into the inner pelvis, where it is difficult to recover for ligation.
- Then internally rotate the hip and transect the glutus medius and minimus muscles at the greater trochanter.
- Divide the fascia laterally either above or below the insertion of the tensor fasciae latae muscle.
- Next divide the lower fibers of the gluteus maximus and detach its tendon from its insertion into the linea aspera. Retract the gluteus maximus and identify and ligate the sciatic nerve and divide it as far proximally as possible, but outside the sciatic foramen. Then transect the external rotators of the hip and divide the origins of the hamstring muscles at the ischiatic tuberosity.
- Complete the amputation by transecting the joint capsule and intra-articular ligament as close to the acetabulum as possible (Figure 120.14.B). Ensure good hemostasis.
- Place large suction drains, one deep in the wound and one above the fascia.
- Begin the closure of the wound by suturing the tendons of the glutei medius and minimus to the transverse acetabular ligament. Suture the gluteus maximus origins of the hamstring muscles at the ischiatic tuberosity.

**Figure 120.15.** Hip disarticulation. See text for details. A: Skin incision. Start the incision at the anterior superior iliac spine (ASIS) and extend along the inguinal ligament to the anterior superior iliac spine. From there, follow the anterior part of the iliac crest eventually to the mid ileum (Figure 120.15.A).

- For the anterior portion, start the skin incision at the pubic tubercle and extend it along the inguinal ligament to the anterior superior iliac spine. From there, follow the anterior part of the iliac crest eventually to the mid ileum (Figure 120.15.A).
- For the perineal part, abduct the hip and extend the incision from the pubic tubercle vertically through the perineum to the ischiatic tuberosity. Expose the pubic and ischiatic rami, and detach subperiosteally the adductor, hamstring, and perineal muscles originating from them, as well as the corpus cavernosum. Then divide the symphysis pubis. Take care not to injure the urethra.
- To complete the posterior part, roll the patient somewhat forward, and while flexing and adducting the hip, complete the skin incision by extending it from the ischiatic tuberosity laterally along the gluteal crease to the greater trochanter, and from there superiorly to join the anterior incision at the midiliac crest (Figure 120.15.A). Expose the posteroinferior margins of the gluteus maximus, incise its aponeurosis in line with the skin incision, detach its femoral insertion, and reflect...
it and the overlying fat and skin as a composite flap proximally. Identify the gluteus medius, the external rotators of the hip, and the sciatic nerve.

- Identify, ligate, and sharply transect the sciatic nerve and allow it to retract into the pelvis.
- Pass a Gigli saw through the greater sciatic notch; divide the sacrotuberosus and sacrospinous ligaments and divide the ilium just lateral to the sacroiliac joint. This is easier than disarticulating the sacroiliac joint. The joint can be disarticulated or even a portion of the sacrum resected if required to establish a surgical margin.
- Then externally rotate the innominate bone, ligate and divide the obturator vessels and nerve, and transect the psoas muscle at the level of the sacroiliac joint. Divide the hip external rotator muscles close to the ischium.
- Transect the levator ani close to its origin on the ischium and the pubis. This will free the hindquarter (Figure 120.15.B).
- Place a deep and superficial suction drain and begin closure by bringing the posterior skin and muscle flap forward and suturing it to the lateral border of the abdominal muscles and the rectus abdominus muscle. Posteriorly, secure it to the psoas and quadratus lumborum muscles. Use #0 or #1 absorbable sutures.
- Then close the skin loosely (Figure 120.15.C, Figure 120.15.D).

Anterior-Flap Technique

The anterior-flap technique for hemipelvectomy as described by Larsen and Liang (51) requires retention of the femoral nerve and vessels as well as the quadriceps musculature.

- Create the anterior flap by starting an incision at the anterior superior iliac spine, and extend it along the lateral aspect of the thigh to the level of the superior pole of the patella. Then continue the incision transversely across the quadriceps tendon medially to the midline, and subsequently proximally to the groin (Figure 120.16.A).

Figure 120.16. Larsen and Liang (51) modified hemipelvectomy using an anterior quadriceps flap. See text for details. A: Skin incision. B: Remove the innominate bone with osteotomies of the pubic rami and the ilium. C: The anterior quadriceps musculocutaneous flap is supplied by the superficial femoral artery and vein, which are carefully preserved. D: The skin closure. (From Bohne WHO. Atlas of Amputation Surgery. New York: Thieme Medical, 1987:120–124, Fig. 15-6, Figs. 15-10, 15-11, with permission.)

- Develop the musculocutaneous flap from lateral to medial by incising the deep fascia and transecting the quadriceps tendon horizontally. Elevate the quadriceps muscle from the femur, developing the dissection along the vastus medialis.
- Find the adductor canal, transect the sartorius muscle and ligate, and transect the femoral vessels as far distally as possible so that their proximal ends remain with the musculocutaneous flap. With further proximal dissection, take care not to injure the femoral vessels. Only the profunda femoris artery is ligated farther proximally (Figure 120.16.C).
- Then complete the hemipelvectomy as described previously, but exclude the posterior flap, which is replaced by the anterior flap. Removal of the innominate bone can be made easier by osteotomy of the pubic rami rather than by disarticulation of the pubic symphysis (Figure 120.16.B).
- Closure of the amputation is as described previously (Figure 120.16.D).

ERTL OSTEOMYOPLASTIC LOWER EXTREMITY AMPUTATION RECONSTRUCTION (PRIMARY AND SECONDARY)

Despite seemingly well-performed amputations, some patients experience persistent residual extremity pain, swelling, a sense of instability, and an inability to tolerate extended prosthetic ambulation. The residual extremity undergoes atrophy as a result of inactivity and becomes a passive participant in walking. This symptom complex is referred to as the inactive residual extremity syndrome. The Ertl osteomyoplastic lower extremity amputation reconstruction is directed at treating difficult transfemoral and transfemoral amputee symptoms and reversing the inactive residual extremity syndrome (21, 22, 23 and 24). Patients in our transfemoral and transfemoral series were surgically reconstructed after nonoperative and prosthetic modifications were exhausted (22-24).

Transtibial Technique

- Utilize the previous amputation incision for exposure. Isolate the neurovascular structures, and ligate the arteries and veins separately. Distract the nerves and cut them well above the bone level, allowing them to retract into a soft-tissue bed.
- Separate the anterior and posterior muscle groups, exposing the distal tibia and fibula in preparation for forming osteoperiosteal cortical island flaps.
- Elevate the osteoperiosteal cortical island flaps with a 30° to 45° angled chisel from the medial and lateral borders of both the tibia and the fibula (Figure 120.17.A).

Figure 120.17. Ertl osteomyoplastic transtibial amputation reconstruction. A: Transverse section of amputation level, with elevated osteoperiosteal flaps from the medial and lateral aspects of the tibia and fibula. The roof is created with anterior flaps. B: The outer osteoperiosteal flaps are folded over the medullary canals and sutured to one another as well as to the superior flap, forming a closed tubelike structure (osteoperiosteal bridge) and closing the medullary canal. C: The opposing muscle groups are sutured together forming the myoplasty. Muscle rotation may be necessary to completely cover the bridge and anterior tibia. D: The skin is contoured to the underlying myoplasty, avoiding dog-ear formation, creating a smooth surface and interface. E: Completed transtibial reconstruction with mature bridge and reestablishment of the medullary canal.

- Remove approximately 1.5–2 cm of the end of the tibia, and suture the retained osteoperiosteal flaps together in tubelike fashion, forming a bony bridge between the tibia and fibula (Figure 120.17.B).
- To complete the myoplasty, secure the ends of the opposing muscle groups to each other over the end of the bone and the underlying bridge, reestablishing some muscle tension (Figure 120.17.C and Figure 120.17.D).
- Contour the skin to the underlying myoplasty, forming a smooth, cylindrical residual extremity (Figure 120.17.D).

Transfemoral Technique

The transfemoral approach is similar to that for transfemoral reconstruction.

- Expose the distal femur through the previous surgical scar and treat the soft tissues and neurovascular structures as described.
- Elevate and suture together the osteoperiosteal cortical island flaps, covering the open-ended medullary canal. Remove minimal bone after flap elevation (Figure 120.18.A, Figure 120.18.B, Figure 120.18.C, Figure 120.18.D and Figure 120.18.E).
Figure 120.18. Erit osteomyoplastic transfemoral amputation reconstruction. A: A periosteal incision is made. B: Osteoperiosteal flaps are created and elevated. C: The femur is transected below the osteoperiosteal flaps. D: The exposed distal bone surface is freshened with a rongeur. E: The osteoperiosteal flaps are sutured to each other, closing the medullary canal. F: The four major muscle groups are isolated. G: The adductors are sutured to the abductors, incorporating sutures into the periosteal sleeve or through bone holes. H: The extensors are sutured to the flexors, circumferentially covering the medial/lateral myoplasty. I: The skin is contoured to the underlying myoplasty, avoiding dog-ear formation.

- Secure the opposing muscle groups to the distal periosteum and to each other to reestablish muscle length and to stabilize the femoral shaft within the muscle envelope (Figure 120.18.F, Figure 120.18.G and Figure 120.18.H).

Conclusion

We have performed 150 transtibial reconstructions, with a mean follow-up of 9 years and a mean time to reconstruction of 9.5 years. We also performed 74 transfemoral reconstructions, with a mean follow-up of 9.8 years and a mean time to reconstruction of 13.3 years. A 30-point clinical assessment score was used to rate postoperative pain, function, stability, swelling, hours able to wear the prosthesis, and radiographic evaluation. A score of over 25 points was graded as excellent, 20–24 as good, 15–19 as fair, and less than 15 as poor. In the transtibial group, there were 73.3% excellent, 18.7% good, 5.3% fair, and 2.7% poor results, with an overall patient satisfaction of 97%. The transfemoral group had 70% excellent, 20% good, 4% fair, and 6% poor, with an overall patient satisfaction of 94% (23,24).

Closure of the medullary canal in amputated extremities has been shown to improve vascularity to the residual extremity and return an elevated intramedullary pressure to normal (23,24,28,49,54,55). In the transtibial population, medullary closure stabilizes the fibula by forming a bony bridge, thus improving the rotational control of the extremity within the prosthesis. The potential for tolerating end bearing is also enhanced with medullary closure for both transtibial and transfemoral patients. Myoplasty has been demonstrated to improve the arterial supply and venous return of the residual extremity, benefiting vascular amputees as well (21,22,28,30,31,62). Additionally, the osteomyoplasty improves extremity control and strength and can provide a greater surface area for prosthetic fitting. Other authors have demonstrated a more powerful residual extremity that is prosthetically more satisfactory (11,16,17 and 18,49,54,55).

Our efforts with the osteomyoplastic technique are directed at generating an active and functional residual extremity by reestablishing as normal a physiologic environment as possible. It is our feeling that the resultant residual extremity will provide the patient with a more durable limb with improved stability and proprioception. The residual limb is more powerful and prosthetically provides better adherence to the socket. No unnecessary bone length is removed to achieve the end result, but we do not hesitate to sacrifice length when an increase in function can be achieved. We have successfully applied this reconstruction to both primary and secondary amputations.

POSTOPERATIVE CARE AND REHABILITATION

Four types of dressings have been recommended following amputation: soft dressings, soft dressings with pressure wrapping, semirigid dressings (56), and rigid dressings. Each has advantages and disadvantages. The rigid dressing leads to the most successful early maturation of the stump. Indeed, in well-vascularized amputation stumps, the rigid dressing can be combined with an immediate postoperative fitting that will allow early weight bearing (8). However, the rigid dressings do not allow easy access to the amputation wound.

The application of an immediate postoperative prosthesis (IPOP) can be considered for all levels of the lower extremity amputation. Use the IPOP with caution in dysvascular amputees, as excessive pressure may lead to wound necrosis. Potential advantages include decreased postsurgical edema, a decreased incidence of thromboembolic disease, less pain, protection of the stump wound, and earlier mobilization of the patient and fitting of a pylon prosthesis, which enhances rehabilitation and is psychologically good for the patient.

Apply the rigid dressing immediately postoperatively in the operating room. Cover the wound with a sterile dressing and a sterile stump sock. Fill the area between the amputation wound and the cast with either fluffed gauze or a premanufactured polyurethane foam cup. Pad bony prominences with strips of felt, and over this apply an elastic plaster-of-Paris bandage to gently compress the area of the amputation wound. In the below-knee amputation, apply the cast to above the knee and keep the knee at approximately 10° to 20° of flexion. Incorporate into the cast a suspension strap for a waist belt as well as an attachment plate for the prosthesis that holds the prosthetic foot.

Experience in applying the IPOP is extremely important, not only for the surgeon and prosthetist but also for the physical therapist who has to supervise the early partial weight bearing (25). Delay weight bearing in dysvascular amputees. Removable rigid dressings have been devised. After 2 weeks at the most, remove the circular rigid dressing for wound inspection and reaplication.

The rigid dressing prevents excessive postoperative edema. This advantage is lost in soft dressing. If a soft dressing with pressure wrapping is used, apply the elastic bandage with care to avoid excessive compression and strangulation of the residual limb.

In a semirigid dressing, use the same inner sterile dressings as for the rigid dressing; however, the outer layer of this dressing consists of Unna paste bandages, which have to be held in place with a stockinet. This type of dressing has the same advantage of preventing excessive postoperative edema as the rigid dressing but does not allow any attachment of the provisional prosthesis.

PITFALLS AND Complications

Infection

Infection after amputations is uncommon and does not occur at a higher incidence than after normal elective surgery when amputations are performed in the absence of preexisting vascular disease or infection in the extremity. The incidence of infection, however, is much higher when amputation is performed in the presence of active infection in the extremity, particularly when the level of amputation is close to the site of infection. In dysvascular amputees, occasionally too distal a level of amputation is selected in spite of preoperative studies indicating that the level of amputation is appropriate.

In our experience, there is a significant incidence of stump complications in amputations performed for open fractures of the tibia secondary to high-velocity crush injuries, when the open fracture wound has gone on to progressive necrosis and infection. These tend to occur in young active patients, so there is a tendency to try to preserve a below-knee level, which may lead to amputation through marginal tissues. The risks of stump wound breakdown and infection in these cases can be minimized by careful preoperative workup to ensure that the amputation is occurring through viable tissue, and by performing staged amputations. The initial stage of the amputation can be a simple guillotine-type amputation, followed by definitive amputation with or without primary closure, or the initial amputation can be with the usual flaps but be left open and then closed secondarily when it is evident that the tissues are viable and infection is not present.

Stump-wound Breakdown

The most common cause of stump-wound breakdown is infection, but necrosis of wound edges as well as of underlying muscle can occur in amputation for peripheral vascular disease because of inadequate vascularity at the level of amputation. Current techniques for evaluating extremity perfusion (as discussed previously) have lessened this risk, but in spite of the best of care breakdown still occasionally occurs. Closure of the wound under tension predisposes to breakdown. This can be
avoided by always closing stumps loosely, since this allows accommodation for postoperative swelling. If revision of the level of amputation to a more proximal level may result in loss of the knee joint or preclude the use of a prosthesis, then reconstructive options such as free microvascular transfer of tissues and Ilizarov bone transport methods may be indicated to preserve function in young active individuals.

**Neuromas**

All nerves that are transected form neuromas, but these are only occasionally painful. Isolating all superficial and deep nerves, gently applying traction to them, and cutting them with a sharp, fresh blade to allow them to retract into soft tissue where the prosthesis will not bear on the nerve end will avoid most problems with neuromas. Treat neuromas initially nonoperatively, with adjustments of the prosthesis and desensitizing techniques in physical therapy. If a neuroma is refractory to nonoperative treatment, explore the nerve, and transect it deeper in soft tissues where it will not be a problem.

**AUTHORS' PERSPECTIVE**

Amputation of any part of the body is a severe emotional as well as a physical trauma. One of my patients told me on the day after the operation, “Part of me has died. When is the rest to follow?” To overcome this feeling of depression and disability, the amputation should be undertaken with a view toward the postoperative life of the patient. The patient must be the most important member of the team that is undertaking the rehabilitation after the amputation.

Certain principles have emerged: Achieving an end-bearing limb remnant in the very young and the very old is important. In the growing individual, the reason for the end-bearing stump is to prevent bony overgrowth, which can require numerous revisions of the amputation. Also, in our experience, the patellar-tendon-bearing prosthesis in the growing individual often leads to the development of a patellaralta, which in turn, is frequently the cause for recurrent dislocation of the patella. In the very old, the end-bearing prosthesis makes rehabilitation considerably easier, and ultimately the prosthesis is more comfortable than after diaphyseal amputations.

Another principle is the preservation of the knee joint. The new prosthetic components have made the use of the below-knee prosthesis easier and more satisfactory than in times gone by. Indeed, many of our younger patients have returned to high-achievement sports. In older below-knee amputees, energy consumption is much more favorable than in above-knee amputees of similar age, allowing them to participate in physical activities with greater ease.

Thus, a conservative approach to amputation, saving as much of the limb as possible as long as the disease process allows, is highly desirable. In lower extremity amputations, this is particularly obvious when comparing internal hemipelvectomy with hindquarter amputation.

**CHAPTER REFERENCES**

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

INTRODUCTION

Upper-extremity amputations, excluding finger amputation, account for 15% to 20% of major extremity amputations. More than 90% of all upper-extremity amputations are a result of trauma, and most of these occur in men between the ages of 20 and 40 years (1). Limb-sparing surgery for primary bone and soft-tissue sarcoma of the upper extremity is possible in the majority of patients, although amputation may still be necessary for local control or palliation in 5% to 10% of patients with malignant tumors (18). Less common causes of upper-extremity amputation are peripheral vascular disease, congenital malformations, neurologic disorders, and severe infections.

The loss of an upper extremity has more devastating consequences than the loss of a lower extremity. Upper-extremity amputations are most common in young male trauma victims, in whom the loss profoundly affects function and self-image. Despite improvements in materials and design, long-term use of prosthetics by upper-extremity amputees is only about 50%. Prosthetic use is reduced in patients with higher levels of amputation, those with brachial plexus injury, and when initiation of prosthetic limb rehabilitation is delayed (4,12,13,23).

INDICATIONS

Trauma is the most common indication for upper-extremity amputation. Acutely severed, crushed, or mangled limbs may require immediate amputation (19). Irreversible brachial plexus injuries resulting in a flail, useless limb may come to amputation following the acute injury period. Malignant bone or soft-tissue tumors that contaminate or encase major nerves or vessels may not be amenable to limb salvage. Tumors with extensive involvement of the carpal tunnel or antecubital fossa may require amputation to eradicate the tumor locally. Peripheral vascular disease that cannot be corrected or reconstructed may require amputation, particularly in the case of diabetes (10).

TRAUMA

Before the development of optical magnification and microsurgical technique, proximal arm replantation was accomplished with limited success (14). Application of microsurgical vascular and nerve repair has allowed successful replantation of more distally severed arms and fingers. Preservation of the arm or hand even with limited sensation or function is often superior to an insensate prosthetic limb. Specific indications for digit replantation have been developed as limitations in function of the replanted part have become better appreciated (6,8,24). Absolute and relative contraindications for limb replantation are listed in Table 121.1. Limb replantation at the transhumeral level is valuable in recovering function of the elbow in most patients; however, more distal recovery is less predictable. Replantation at this level may permit conversion of an above-elbow amputation to a below-elbow amputation, thereby improving rehabilitation potential and success of prosthetic use (22). Short residual limbs following traumatic amputation in selected individuals can be lengthened using bone distraction techniques (20).

Table 121.1. Contraindications to Replantation

BRACHIAL PLEXUS INJURY

Brachial plexus injury most commonly occurs in young men following motor vehicle accidents or industrial or farming injuries. The prognosis for recovery depends the location of the injury and its extent. Nerve root avulsions are not repairable but may be reconstructed with distal neurorlarization and muscle transfer, provided sufficient donors are available. Extensive, multilevel nerve root avulsions may result in a flail limb with little potential for recovery. Computed tomography contrast myelography, axon response to intradermal histamine, electromyography, somatosensory evoked potentials, and magnetic resonance imaging may be useful means to identify nerve injury location (11,15). Early repair and intraoperative nerve conduction and stimulation have been advocated to improve results of brachial plexus repair (8,15).

Signs of irreversible complete brachial plexus injuries include (17):

- Absence of any clinical return of function after 1 year
- Three or more pseudomeningoceles on myelography
- Absence of voluntary action potentials in the area of C-5 to T-1 on repeated electromyographic examinations
• Positive histamine tests in the area of C-5 to T-1

If an irreversible injury occurs, consider early above-elbow amputation and prosthetic rehabilitation. Within 3 to 6 months after a complete brachial plexus injury the patient becomes a “one-handed” person, transferring most activities from the injured limb to the normal limb. More effective rehabilitation and better prosthetic compliance have been achieved with early above-elbow amputation and prosthetic training, avoiding the development of single-hand function patterns (15, 16, 17). Upper-extremity amputation for intractable pain following brachial plexus injury is not successful in the majority of patients (3) (see Chapter 60).

MALIGNANT MUSCULOSKELETAL TUMORS

The majority of bone and soft-tissue sarcomas in the upper extremity, excluding the hand, can be resected with wide margins that spare the limb without adversely affecting survival (18). Bone and soft-tissue reconstruction using tendon transfers, nerve and vein grafts, and free microvascular tissue transfer allow both functional and cosmetic reconstruction in the majority of cases. Tumors that cannot be resected without the sacrifice of multiple major nerves, or without excessive risk of local recurrence, usually require amputation. The level of amputation must provide margins that preclude local recurrence regardless of the functional impairment that results from a more proximal level of amputation. See Chapter 126 and Chapter 128.

SURGICAL TECHNIQUES

UPPER-EXTREMITY AMPUTATION

- Perform upper-extremity amputations at the most distal level compatible with uncomplicated wound healing. Handle soft tissues atraumatically.
- Sharply divide nerves and allow them to retract to provide adequate soft-tissue coverage. Avoid electrocautery in the vicinity of nerves.
- A tourniquet may be used; however, exsanguination is contraindicated in limbs being amputated for infection or tumor.

BELOW-ELBOW AMPUTATION

If the vascular status of the limb is satisfactory, amputation at the most distal level provides the optimal stump for prosthetic use. If the vascular status of the limb is compromised, healing at the distal third of the forearm may be impaired owing to the lack of well-vascularized muscle deep to the subcutaneous tissue. A tourniquet may be used.

- Fashion equal anterior and posterior skin flaps (Fig. 121.1), and ligate the radial and ulnar arteries.

![Figure 121.1. A below-elbow amputation, demonstrating equal dorsal and volar flaps.](image)

- Identify the major nerves (i.e., radial, ulnar, median), sharply divide them as far proximally as possible, and allow them to retract into the soft tissues.
- Section the radius and ulna proximal to the most proximal portion of the skin incision, and smooth the rough edges with a rasp or rongeur.
- Perform a myoplasty closure. If the amputation level is proximal to the myotendinous junction of the flexor and extensor tendons of the forearm, suture the palmar compartment muscles over the end of the bone to the extensor compartment.
- The most proximal level compatible with below-elbow prosthetic fitting is the level of the biceps tendon insertion on the radius. If circumstances require amputation at this level, releasing the distal 2.5 cm of the biceps tendon provides a longer stump for prosthetic fitting.
- If the level of amputation is in the distal one third of the forearm, bring the tendinous portion of the flexor digitorum superficialis over the end of the bone and suture it to the extensor compartment fascia.
- Obtain hemostasis. If necessary, use a drain. Close the wound without tension, and apply a bulky compressive dressing.

ELBOW DISARTICULATION

Amputation through the elbow has the same advantages as a through-knee amputation in the lower extremity. The bulbous distal humerus allows suspension of a prosthesis. The long lever arm allows humeral rotation of the prosthesis, alleviating the need for the mechanical turntable required in more proximal brachial amputations. However, the soft tissue is thin at the elbow, and fitting of the prosthesis must be exact.

- A sterile tourniquet may be used. Fashion equal anterior and posterior flaps, with the posterior flap extending to a point 2.5 cm distal to the olecranon and the anterior flap extending to the biceps insertion on the radius.
- Ligate the brachial artery. Sharply divide the radial, ulnar, and median nerves proximally. Allow them to retract into soft tissue.
- Disarticulate the elbow by dividing the insertion of the biceps (i.e., radius) and the insertion of the brachialis (i.e., ulna) anteriorly and by dividing the triceps tendon at its olecranon insertion. Release the medial flexor and pronator mass from the medial epicondyle, and divide the extensors from the lateral humeral epicondyle.
- Perform an anterior capsulotomy, and remove the forearm, leaving the articular surface of the distal humerus intact.
- Bring the triceps tendon anteriorly and suture it to the tendons of the biceps and brachialis muscles over the trochlea of the humerus. Place a drain and close the wound without tension. Apply a bulky compressive dressing.

ABOVE-ELBOW AMPUTATION

To allow fitting of an above-elbow prosthesis, which includes an elbow lock mechanism for flexion and extension and an elbow turntable for rotation, perform above-elbow amputations 3.8 cm proximal to the joint. Amputation at the level of the surgical neck of the humerus functions as a shoulder disarticulation; however, this level has the cosmetic advantage of preserving normal shoulder contour.

Midarm Amputation

- For amputations through the midbrachium (Fig. 121.2), fashion equal anterior and posterior flaps.

![Figure 121.2. An above-elbow amputation using equal anterior and posterior flaps.](image)
Identify and ligate the brachial artery.
Divide the anterior compartment muscles approximately 1.3 cm distal to the intended level of bone transection. Divide the triceps 5 cm distal to the intended level of bone transection.
Section the humerus and smooth its rough edges with a rasp.
Perform a myoplastie closure, suturing the anterior compartment muscles to the triceps. Close the wound without tension over a drain. Apply a bulky compressive dressing.

Proximal Third Amputation

For amputations through the surgical neck of the humerus, make an incision anteriorly from the coracoid process along the anterior border of the deltoid to the lateral insertion of the deltoid on the humerus. Extend the incision posteriorly along the posterior margin of the deltoid to the posterior axillary fold, and connect the two incisions by an axillary incision.
Ligate the cephalic vein. Release the deltoid muscle from its humeral insertion, and reflect it proximally. Release the pectoralis major muscle from its humeral insertion, and reflect it medially (Fig. 121.3).

Figure 121.3. A proximal humeral amputation using the anterior approach.

Identify the neurovascular bundle, and ligate the axillary artery. Sharply divide the musculocutaneous, median, ulnar, and radial nerves, and allow them to retract proximally.
Divide the teres minor and latissimus dorsi muscles close to their humeral insertion. At a point approximately 2 cm distal to the intended bone section, divide the coracobrachialis and biceps muscles, and reflect them distally.
Amputate the humerus at the surgical neck. Suture the biceps and coracobrachialis muscles to the triceps muscle over the stump of bone. Trim the deltoid laterally, and suture it medially. Place appropriate drains, and close the skin without tension.

Shoulder Disarticulation

Begin an anterior incision at the coracoid process, and proceed distally along the anterior margin of the deltoid to its humeral insertion (5). Continue posteriorly along the posterior margin of the deltoid, and connect the anterior incision with a posterior incision across the axilla.
Identify the neurovascular bundle in the interval between the coracobrachialis and the short head of the biceps, and ligate and divide the axillary artery and vein.
Sharply divide the median, ulnar, and musculocutaneous nerves, and allow them to retract into soft tissue.
Detach the deltoid from its humeral insertion, and retract it along with its overlying skin proximally. Release the coracobrachialis and short head of the biceps from their origin from the coracoid, and release the humeral insertion of the pectoralis major.
Externally rotate the arm, and divide the anterior joint capsule and subscapularis muscle. Internally rotate the arm, and divide the short external rotators and the teres major.
Divide the triceps and inferior capsule, and remove the arm.
Suture the muscle ends into the glenoid to fill dead space. Bring the deltoid with its overlying skin inferiorly, and suture it inferior to the glenoid to the margin of the posterior axilla incision, completing the procedure.

Scapulothoracic Disarticulation

Begin the incision lateral to the clavicular insertion of the sternocleidomastoid muscle, and extend the incision distally along the clavicle to the acromioclavicular joint over the acromion to the spine of the scapula and posteriorly along the vertebral border of the scapula (5, 7).
Begin the lower incision at the middle third of the clavicle. Proceed distally to the deltopectoral groove and cross the axilla horizontally, and join the first incision posteriorly at the spine of the scapula.
Release the pectoralis major from the clavicle, and divide the clavicle lateral to the insertion of the sternocleidomastoid. Excise the clavicle to the level of the acromioclavicular joint.
If necessary, ligate the external jugular vein and release the pectoralis major and minor from their insertions, exposing the neurovascular bundle.
Ligate and divide the subclavian artery and vein. Section the components of the brachial plexus, and allow them to retract.
Release the latissimus dorsi and axillary fascia from the humerus, allowing the limb to fall posteriorly. Hold the arm across the chest, and from superiorly to inferiorly divide the remaining muscles that fix the shoulder to the scapula. Divide the muscles that hold the scapula to the thorax, starting with the trapezius and continuing through the omohyoid, levator scapulae, rhomboid major and minor, and serratus anterior.
Remove the arm and scapula.
Suture the remaining muscle over the lateral chest wall, and close the skin flaps over suction drainage.

Resection Replantation

Resection replantation has been described by Windhager et al. (21) and is analogous to a Van Ness rotation plasty of the lower limb.
Resect the tumor-bearing portion of the arm as a cylindrical segment, including prior biopsy sites and all contaminated structures.
Dissect uninvolved vessels or major nerves from the tumor-bearing segment through longitudinal incisions, if this can be done with wide margins (21).
Accomplish reconstruction by limb shortening, osteosynthesis, and vascular, nerve, and soft-tissue repair. This is an effective procedure for malignant tumors that offers an alternative to amputation in carefully selected patients.

Postoperative Care and Rehabilitation

After surgery, a patient with an upper-extremity amputation may be treated with a rigid dressing and early prosthetic fitting, as described by Burkhalter (4). Approximately 50% of upper-extremity adult amputees are rehabilitated with functional prosthetics (23). Before initiating prosthetic fitting and training, consider the age, extremity dominance, occupation, and psychosocial status of the patient (17, 18). Bilateral upper-extremity adult amputees should be fitted with at least one functional prosthesis, usually one that is externally powered.

There are two major categories of upper-extremity prostheses. The conventional body-powered prosthesis relies on proximal shoulder girdle muscles to provide the force to power a terminal grasp device through a system of harnesses and cables. Depending on the level of amputation, the elbow and wrist “joints” must be positioned manually by the contralateral normal limb. Myoelectric prostheses rely on electrical potentials in active muscles in the stump to activate electrodes in the prostheses,
which switch electrical motors on and off within the device. These prostheses are expensive, heavy, and require frequent maintenance.

Regardless of the type of prosthesis used, the timing of initial prosthetic fitting determines the ultimate success of rehabilitation. Malone demonstrated in a series of upper-extremity amputees that prosthetic fitting within 1 month of amputation resulted in a 93% success rate of prosthetic rehabilitation (26 of 28 patients) (12, 13). Among upper-extremity amputees fitted later than 1 month after amputation, only 42% (9 of 19) achieved prosthetic rehabilitation. Although advocates of rigid postoperative dressings note higher rates of early prosthetic use, their use should be limited to those patients with normal sensation and well-vascularized soft tissues that have not been injured by trauma.

Chapter 122

PRINCIPLES OF AMPUTEE PROSTHETICS

A prosthesis cannot come close to replacing a missing limb from either a functional or a cosmetic viewpoint. In the last decade, however, modern technology and improved materials have closed the gap considerably (1,3,4,11). The result is that motivated individuals with no additional health problems can now expect to regain a degree of function that will allow them to pursue an active lifestyle of their choice. Limitation of the maximum performance possible should not be a consequence of either an inadequate prosthesis or negative expectations of the health care providers. Patients' cooperation and positive attitude are critical.

To regain an active lifestyle, patients must be educated about the operative procedure, receive psychosocial support, be fitted with a comfortable prosthesis, and engage in aggressive rehabilitation. Good communication between members of the health care team and patients cannot be emphasized strongly enough. Encouragement and positive reinforcement go a long way toward helping patients achieve their goals (see Chapter 120 and Chapter 121 for discussion of the principles of lower- and upper-extremity amputations, respectively).

LOWER-EXTREMITY AMPUTATIONS

AMPUTATION SITE VERSUS FUNCTION

Some of the older rules for limb length no longer apply in determining the level of amputation for prosthetic fit (12,13,17). For instance, when a lower-limb prosthesis is fitted, adequate length of the residual limb plus modern components can often result in significantly better function than an amputation that results in a longer lever arm with the use of more basic and primitive components (16,18).

Partial Foot Amputation

The main advantage of a partial foot amputation is the ability to walk without a prosthesis. The disadvantages at this site include the difficulty in making a cosmetic prosthesis with “toe off” function, the uneven gait that results without toe-off function, the tendency to develop an equinovarus deformity in the residual foot stump, and the limited foot components available (Fig. 122.1).

Figure 122.1. A: Midfoot amputation with a shoe insert prosthesis. B: An ankle–foot prosthesis for amputations through the hindfoot other than a Syme’s amputation. (From Dee R, Mango E, Hurst LC. Principles of Orthopaedic Practice. New York: McGraw-Hill, 1989:365, with permission.)

Syme’s Amputation

Syme’s amputation retains the heel pad. The advantage of this technique is that limited ambulation is possible without a prosthesis. Its disadvantages include a less cosmetic prosthesis due to the thick ankle required to accommodate the stump, the limited foot components available, and the limited amount of energy storage within these components (Fig. 122.2).
Transtibial Amputation

In elective surgery where the amputation site can be selected, it is preferable to have enough space distally to incorporate appropriate prosthetic components for best function and cosmesis, while maintaining adequate length of the residual limb. Ideally, the length of tibia from the mid-knee joint to the distal end should be no less than 4 in. (10 cm) and no more than 7 in. (17.75 cm). If the tibia is too long, the choice of components is limited and cosmesis may be compromised. The space from the floor to the end of the residual limb (after the incision is closed) should be at least 12 in. (30.5 cm), but not if it will leave the length of the tibia less than 4 in. (10 cm).

Through-the-knee Amputation

Through-the-knee amputation provides the potential of end bearing in the prosthesis, a long lever arm, and condylar suspension. A knee disarticulation is particularly good for patients with poor gait and neuromuscular control. It is important in children with growth potential who need their distal femoral epiphysis to retain stump length. The disadvantages of this technique include the limited knee components available (including a button rotator), the differences in the center of rotation of the two knees, poor cosmesis due to the large femoral condyles, and atrophy of the thigh that occurs with condylar suspension. High-performance function is better achieved with a long transfemoral amputation and a prosthesis with modern knee components.

Transfemoral Amputation

When there is a choice of amputation site, a space of 4 in. (10 cm) from the knee center to the distal end of the residual limb is optimum, as long as this is not greater than one-third the length of the femur. This space permits a greater choice of knee and other components, and function and cosmesis are improved.

PREPROSTHETIC CARE

The goals after surgery for lower-extremity amputations in which there is a residual limb are listed in Table 122.1. These can be achieved through one of several methods: an immediate postoperative prosthesis or serial wrapping of the residual limb with an elastic bandage or an elastic shrinker. The overall aim is to reduce postsurgical edema. This in turn reduces postsurgical pain, minimizes later phantom pain, increases circulation (therefore hastening healing), and prepares the operative site and residual limb for a preparatory prosthesis. Where possible, elevation of the affected limb can also help reduce edema, although this must be accompanied by immediate aggressive physical therapy to prevent contractures of the surrounding joints. When there is no residual limb, the postsurgical goals are fewer (Table 122.1). Methods to reduce postoperative edema and prevent breakdown of the incision in patients include turning the patient onto the sound side and early mobilization.
Immediate Postoperative Prosthesis

An immediate postoperative prosthesis (IPOP) is a specialized dressing covered by a plaster cast molded to provide weight-bearing areas to enable patients to ambulate as soon as it is practical. The IPOP incorporates an adapter into its distal end that has a removable pylon with a prosthetic foot attached.

An IPOP is intended to control edema, promote ambulation, and prevent flexion contractures, as well as to keep patients from “waking up without a leg.” The prosthetist applies a specially padded and molded cast in the operating room after the surgical dressings have been applied. The advantage of this technique is that the cast initially prevents postsurgical edema, promoting wound healing and reducing pain. The cast also protects the residual limb, prevents flexion contractures in the surrounding joints, and molds the residual limb while compression is maintained. The difficulties with this technique are that the cast loosens as soon as the edema subsides and the subsequent pistoning action can cause tissue breakdown. The cast must either be continually replaced or be removable so that additional socks or fillers can be used to maintain compression. Other difficulties involve the heaviness of the cast, which prevents movement of the contained joints, impedes walking, and leads to muscle atrophy. The cast must be removed to monitor wound healing, frequently needs to be reapplied to contain compression, and is not cosmetic. Auxiliary suspension may be required (Fig. 122.5).

The advantage of an elastic compression bandage is that it can be reapplied whenever it becomes loose and therefore compression can be kept constant. Patients can be taught to wrap the limb, and compression can be applied only in areas where it is needed (Fig. 122.6 and Fig. 122.7). The problem with a compression dressing is that it may be wrapped too tightly, causing pain or tissue breakdown, or too loosely to be effective. Patients may have difficulty wrapping it themselves, and it may cause window edema when applied incorrectly or unevenly.

Elastic shrinkers, when applied correctly, provide overall compression and allow wound monitoring. They may be difficult to apply correctly in some individuals.
however, and may not put direct pressure over areas where it is needed (Fig. 122.8).

Figure 122.8. Elastic shrinker for a transfemoral residual limb. (Courtesy of the Joyce Center, Manhasset, NY.)

The choice of these various techniques depends on the ability and cooperation of a patient, the length of the limb, and careful evaluation of the goals for the individual.

Secondary goals include the maintenance of range of motion in the surrounding joints (hip and knee), prevention of muscle atrophy, and elimination of pain. To achieve these, physical and occupational therapy consisting of range-of-motion, stretching, and strengthening exercises should be initiated as soon as possible. An early fit of the prosthesis will be beneficial.

RATIONAL FOR A PREPARATORY PROSTHESIS

A preparatory prosthesis is fitted to a patient while the amputated limb undergoes normal maturational shape changes after surgery. Fitting should be started after the sutures or staples have been removed and the incision has healed.

In the lower limb, the primary purposes of a preparatory lower-extremity prosthesis include controlling postsurgical edema, minimizing the loss of muscle mass and strength, preventing joint contractures, and allowing patients to ambulate. Historically, preparatory prostheses were made with the simplest components, worn with wide, loose socks, and suspended with straps and belts. To accommodate postsurgical shrinkage and muscle atrophy of the residual limb, the ply of the socket was increased until the size of the limb stabilized, at which time the definitive prosthesis would be fabricated. However, new socket materials and designs, along with modern components and more aggressive training, promote the use of remaining muscle so that after postsurgical edema has subsided, there is often little or no muscle atrophy. If appropriate for an individual, one of several types of suction suspension can often be used as soon as the incision is completely healed, replacing the socks and belts. With the use of more sophisticated components, correct gait can be taught immediately to avoid retraining once the definitive prosthesis has been fit.

After the socket is carefully fitted and fabricated and the components are aligned, patients should be taught how to use the prosthesis. Limit ambulation to partial weight bearing, and check the residual limb frequently; graduate to total weight bearing as tolerated. How long this takes will depend on the fit of the prosthesis, as well as the strength, coordination, ability, and determination of the patient.

Although the residual limb will continue to mature and change shape for the lifetime of individuals, the most dramatic changes occur during the first 3–6 months. Constantly monitor and modify the socket, or change the sock ply to accommodate these changes to maintain fit. Make patients aware that this is quite normal. The definitive prosthesis is fabricated once these changes have stabilized.

PROSTHETIC FITTING AND ALIGNMENT

When fitting a first prosthesis, the prosthetic team thoroughly examines a patient and evaluates the medical history. A detailed explanation of the process of prosthetic fitting, preferably accompanied by written materials, is given to the patient. A prescription recommendation is sent to the referring physician by the prosthetist with a request for a letter of medical necessity. The primary concerns are comfort, function, and cosmesis. The prescription recommendations depend on the patient’s age, previous activity level, hoped-for outcome, length of residual limb, medical history, and reimbursement limitations. The prescription should include type of prosthesis (endoskeletal versus exoskeletal), type of suspension, socket design, materials, choice of components, and cosmetic finish.

The comfort of the socket is always the primary concern and depends on the skill of the person taking the measurements or the impression of the residual limb, as well as on the materials used. Initially, measurements are taken, and a negative wrap of the residual limb (or digitized equivalent; see below) is made. A positive model is produced from the impression and modified, and a clear diagnostic socket is formed over that mold. The diagnostic socket is fitted to the residual limb, the fit is checked, and any indicated changes are made to the positive model, with refitting of the socket if necessary. A flexible, total-contact socket is formed within a rigid frame, and the chosen components are aligned so that the foot, knee joint, and so on are in a neutral alignment. The prosthesis is then fitted and dynamically aligned, and initial gait training is performed while the alignment is fine-tuned. After the prosthesis is delivered to the patient for trial use, a protective cosmetic cover is fabricated, and further alignment and fitting changes are made, as necessary, on the basis of continued functional examination.

Although the majority of prosthetists take a cast of the residual limb and manually modify the positive mold to fabricate a socket, an alternative method is the computer-aided design/computer-aided manufacturing (CAD/CAM) system. With this system, information on the residual limb is converted into numerical data, read into the computer by a digitizer (usually from a negative mold), and converted into a three-dimensional image by commercially available software. Modifications to this image are made by the prosthetist; the information is then relayed to the attached carver, which produces the positive model. Thereafter, the processes are similar regardless of whether the manual or the CAD/CAM method is used. A hard, clear diagnostic socket is formed over the model and then fitted on the residual limb. Weight-bearing surfaces and bony or sensitive areas are checked, and any necessary modifications are made to the diagnostic socket before the definitive one is fabricated.

Once the components have been assembled and bench-aligned, a dynamic alignment must be done with the patient wearing the prosthesis. There are two schools of thought concerning alignment: According to one school, the prosthesis is aligned to accommodate any abnormalities in posture, such as flexion contracture, whereas the second gradual corrections in alignment are made simultaneously with aggressive rehabilitation of the patient, until a more correct alignment can be obtained.

Frequent follow-up visits are necessary after delivery of the prosthesis to make the corrections and adjustments that will inevitably be needed as a patient progresses. It is important that patients understand that this is a normal process and that a plateau will eventually be reached where it will only be necessary to have routine checks unless a new prosthesis is fabricated. They must be informed of the importance of maintaining a stable body weight and a regular exercise program. Excessive gain or loss of weight compromises fit and function of a prosthesis. Many of today’s components are designed for a weight range or activity level.

Endoskeletal versus Exoskeletal Prostheses

A endoskeletal prosthesis is made with an internal skeleton of components and a foam outer cosmesis (Fig. 122.9). It is modular in design, thus permitting greater interchangeability. The advantages of the endoskeletal are that changes in alignment can be made with ease at any time during the life of the prosthesis to accommodate changes in posture, gait, or growth. In the modular design, individual components can be changed without remaking the prosthesis. The problems with this technique are that it is more expensive and may require more maintenance.
The exoskeletal prosthesis is often made of wood or polyurethane with a laminated rigid outer shell. Once fabricated, it has limited adjustability without being refabricated. It is less expensive and has a more durable cover than the endoskeletal type. Its disadvantages include no postdelivery accommodation–alignment changes, limited dynamic response capability, and limited component choices. In addition, it is frequently heavier than the endoskeletal prosthesis.

Suspension can be achieved with suction or a sleeve, belt, or cuff strap. The suction technique aims to reduce pistoning in the socket, thus requiring less energy expenditure during ambulation. It promotes venous return and gives patients the feeling that the prosthesis is lighter. In addition, it eliminates the need for uncomfortable belts and straps.

In the transfemoral amputation suction application, the residual limb is drawn into the socket with an elastic bandage or a type of pull sock until the air is displaced through the distal valve hole; a one-way valve is placed in the valve hole to prevent air from reentering the socket. Although it seems easier to lubricate the residual limb and push it into the socket, the result is hammocking of tissues on the distal end and failure to get all the proximal tissue into the socket.

The sleeves are usually made of flexible plastic and surrounded by a rigid frame to support the weight-bearing areas. The quadrilateral socket for the transfemoral amputee is being replaced by one of several versions of ischium-containing designs. Containment of the ischium within this type of socket provides pelvic stability and promotes normal femoral alignment and better function of the remaining intact musculature. Proprioception is also increased.

It is now possible to make more comfortable sockets for higher transfemoral, hip-disarticulation, or hemipelvectomy amputations. The bucket socket is made of laminated silicone or flexible plastic supported by a rigid frame. The new families of silicone or gel socket liners have improved the comfort of sockets.

Components that improve the comfort and function of the prosthesis should be used. It is our opinion that the more debilitated a patient is, the greater is the need for...
help from the prosthesis. The question posed should be, “What can we provide to make walking easier and more efficient for a person?” rather than making the assumption that this person is not “a candidate for ambulation.” The components requiring consideration are the hips, the knees, and the feet.

The hip joints are limited to single-axis joints with an extension assist.

Several types of knee joints are available. The single-axis, constant-friction knee is the simplest design. The main drawback for this component is that ambulation is normal only at one speed for a set amount of friction. The safety knee with constant friction is designed so that the patient’s weight locks the knee in the standing position. The polycentric knee joint has hinges external to the prosthesis and was originally designed for through-the-knee prostheses. It provides better control during standing and the stance phase of gait. The swing phase may be controlled mechanically or with a hydraulic cylinder. Hydraulic knee joints, which are the most sophisticated on the market to date, control both swing and stance phase and are velocity-sensitive. Table 122.2 specifies the indications for use of the various types of prostheses, together with advantages and disadvantages.

**Table 122.2. Knee Joints for Above-Knee Prosthesis**

The prosthetic ankle–foot systems comprise several main groups: articulated ankle joints, dynamic-response and energy-storing foot, and nondynamic-response and/or energy-storing feet. The simplest and cheapest combination is the nonarticulated ankle and the nondynamic-response foot, called the solid ankle-cushion heel (SACH) foot; it is also the least efficient.

The combination of a solid ankle and a dynamic-response foot allows maximum loading of the toe section of the foot during “rollover.” Similar to the action of a coiled spring, when the pressure or loading is removed, the toe section springs back to provide push-off. The most extreme version of this is found in a foot–ankle and shank made of carbon fibers, in which the loading action or energy storage is also carried out in the shank. The method of loading the toe must be taught, or the benefits will not be experienced. In fact, users may complain that the toe is too stiff, and reject the foot.

An articulated ankle joint, useful for people who spend considerable time walking on uneven ground, is heavier than other prosthetic feet and requires more maintenance. An added disadvantage is that even if it is combined with a dynamic-response foot, the action of the ankle precludes loading the toe to provide push-off. The various options for lower-extremity prosthetic components are shown in Figure 122.12.

**Figure 122.12. Choice of components for the transfemoral amputee. (From Braddon RL. Physical Medicine and Rehabilitation. Philadelphia: W.B. Saunders, 1996:307, with permission, University of Texas Health Science Center at San Antonio.)**

**REHABILITATION AND TRAINING**

A successful outcome depends as much on rehabilitation and training as it does on the fabrication and fitting of a prosthesis. Studies show that energy expenditure during ambulation is higher for amputees than for nonamputees (2,6,7,9,10,14,16,19). Factors affecting energy expenditure include the length of the residual limb, unilateral or bilateral amputation, the reason for amputation, the choice of prosthetic components, the weight of the prosthesis and whether the weight is concentrated distally or proximally, the efficiency of the suspension aids for the prosthesis, the symmetry of the gait, the state of the cardiovascular system, the patient’s age, and the general state of physical fitness (5,11).

The net energy cost of ambulation, or the amount of oxygen required per kilogram of body weight per meter walked (ml O₂/kg/m), is higher than normal in most unilateral amputees and increases as the amputation level gets higher. In addition, the preferred speed of walking becomes slower (8). The weight of the prosthesis can contribute to this increased energy cost, particularly if the extra weight is distal. Suction suspension can make a prosthesis feel lighter, while pistoning between residual limb and socket creates a pendulum effect. Careful choice of components is therefore very important. A less symmetric gait also requires more energy. Elderly individuals who have an amputation for vascular reasons are less efficient partly because of the aging process but also as a result of arteriosclerotic heart disease, peripheral vascular disease, or diabetes, which all inhibit the efficient transfer of oxygen to the muscles.

Start balancing, stretching, and muscle-strengthening exercises as soon as possible after amputation to maintain flexibility, prevent flexion contractures, and preserve muscle strength and mass. In addition, make an aerobic conditioning program a part of the rehabilitation process whenever possible. This combination will have the dual effect of strengthening the cardiovascular system so that there is more efficient transfer of oxygen and building up muscles to use that oxygen (8). Once a prosthesis has been fitted, patients should do all physical therapy and exercise programs with the prosthesis on.

Correct-gait training starts with the first step taken in the prosthesis. Even if only partial weight bearing is allowed, encourage amputees to stand up straight and take even strides. It is easier to teach someone correctly from the beginning than to try to correct a bad habit later, just as it is easier to prevent a flexion contracture than to correct it. Although walking frames are frequently used, particularly by the elderly, they have the disadvantage of encouraging users to walk unevenly. Typically, a long step is taken with the sound side to the front of the frame, and the prosthetic side is then only brought even with the sound side. If a walker must be used for stability, it should be moved forward before each footstep to allow room for the feet to be placed sequentially one in front of the other.

Fear of losing balance and falling is the main concern of new amputees. Functional muscle-strengthening exercises—those that are carried out standing on the prosthetic side while exercising the sound side—are as important as exercises carried out on the affected side.

We have observed that, unless taught otherwise, many amputees will stand and walk with their affected-side hip behind their sound-side hip, even though the shoulders will remain straight. The result is that the stride length is uneven, with the stride taken with the prosthesis being longer than that with the sound side. Use of an energy-storing/dynamic-response foot will in effect prevent loading of the toe and the resulting toe push-off. It has therefore been our practice to gait-train our clients in the following way:
At heel strike on the affected side, contract the muscles on that side from the gluteals to the end of the residual limb and push down and back.

Move the affected hip forward until the foot is flat on the floor while rolling forward (not up) onto the toe of the sound side and starting the sound-side swing phase.

Move the affected hip farther forward, feeling the stretch in the hip flexors, compressing and loading the prosthetic toe while completing the swing phase of the sound side.

At heel strike on the sound side, relax the muscles on the affected side. The prosthetic toe will push off, initiating a knee bend and affected-side swing-through.

In this way, the patient’s own body weight is doing the work of loading the prosthetic toe. It is also important to maintain normal upper-body movement, that is, equal arm swing and torso rotation. Although it seems to be very difficult work initially, the result is a more even gait pattern and less work. Figure 122.13 and Figure 122.14 depict the appropriate activity of the muscles during gait for transtibial or transfemoral amputation.

![Figure 122.13](image1.png)

*Figure 122.13. Muscle activity in the flexors and extensors of the hip and knee during the gait cycle for a transtibial amputee.*

![Figure 122.14](image2.png)

*Figure 122.14. Muscle activity flexors and extensors of the hip in a transfemoral amputee during the full-gait cycle.*

Unless contraindicated, a supervised aerobic conditioning program will improve the endurance of all lower-extremity amputees—it is not only for athletes. In our experience, as long as a prosthesis fits well, a tailored exercise program can be undertaken by individuals with diabetes and circulatory insufficiency, and they will benefit. Stationary bicycles, rowing machines, or upper-body ergometers can all be used, although the treadmill is the piece of equipment of choice because it also improves walking. Ideally, in addition to stretching and muscle-strengthening exercises, these individuals should exercise for a minimum of 20 minutes at least three times per week at an elevated heart rate determined by their physicians.

**GAIT ANALYSIS**

After a patient has had some early experience in the prosthesis, members of the prosthetic team must observe the patient’s gait on a straight-level walkway to be certain that gait abnormalities are not due to inadequate rehabilitation or improper fitting or alignment of the prosthesis. Table 122.3 and Table 122.4 provide an outline of commonly observed gait abnormalities, a description of their characteristics, and common causes that require correction.

![Table 122.4](image4.png)

*Table 122.4. Gait Analysis of the Transfemoral Amputee*
AMPUTATION SITE VERSUS FUNCTION

Upper-extremity amputations include wrist disarticulation, below-elbow amputation, elbow disarticulation, above-elbow amputation, shoulder disarticulation, and forequarter amputation. Wrist disarticulation has the greatest range of extremity motion: flexion, extension, pronation, and supination. It also has a long lever arm for strength and support of distal components, and increased proprioception and function. However, it is more difficult to fit with a myoelectric hand and wrist, and the resulting fit is often longer than the sound side. The choice of components is limited.

The below-elbow amputation provides anatomic ability to pronate and supinate, has a wider range of components available, and can achieve equal length with the sound side. The choice of a myoelectric or body-powered prosthesis is available. This amputation has less range of motion, a shorter lever arm, and less proprioception and function than the wrist disarticulation. Anatomic pronation and supination decrease as the length of the residual limb decreases.

The elbow disarticulation has a long lever arm and potential increased prosthetic range of motion, for the shoulder-to-elbow portion, when fitted with a prosthesis, will be longer than the opposite extremity than with the above-elbow amputation. The increased length at the elbow is due to the components, but casual observers do not detect the discrepancy. Choice of elbow components is limited to body-powered devices.

Nevertheless, the plaster cast of the IPOP is heavy and prevents movements of contained joints, resulting in muscle atrophy. If the cast becomes loose, it can cause tissue breakdown, particularly if it is resting on the transradial area or other proximal joint. The cast is also prone to fall off, particularly with transhumeral amputations, unless auxiliary suspension is used. Use of a cast also prevents monitoring of the incision. Another problem with this technique is that the terminal hook device is not cosmetic. An IPOP cannot be applied over extensive skin grafting and is not useful on very short residual limbs.

The rationale for upper-extremity preparatory prostheses is the same as that for lower-extremity preparatory prostheses.

PREPROSTHETIC FITTING

The goals of prepressthetic care for upper-extremity amputations are the same as those for lower-extremity amputations (Table 122.1).

IMMEDIATE POSTOPERATIVE PROSTHESSES

An IPOP applied to the upper-extremity controls postsurgical pain and edema, improving circulation through reduced edema. Patients benefit psychologically by “waking up with a hand and arm.”

In amputations with a residual limb, a preparatory upper-extremity prosthesis can protect the residual limb from injury, prevent and treat contractures in the contained joints, and initially mold the residual limb. Patients maintain some two-handed function and receive training in the use of a prosthesis. It also allows assessment of a patient's motivation. It can be removed for wound care and helps maintain body symmetry. The IPOP is usually worn only for 2–6 weeks after surgery. It is body-powered rather than myoelectric, and because of its weight, it uses a terminal hook device rather than a hand.

Length, condition, strength, and range of motion of the residual limb are the determining factors in the choice of a prosthetic system. Personal preference and motivation also play a role.

Preservation of length of the residual limb in upper-extremity amputations is critical for maximum function. This differs from the principles for the lower-extremity, where components can be more functional and a long residual limb length is not always beneficial.

Upper-extremity amputations involve several choices:

- Passive, in which the position of the terminal device or more proximal components is changed with a contralateral hand
- Body-powered, in which gross body movements activate cables for function
- Myoelectric, which is battery-powered and computer-driven
- Hybrid system, which is a combination of body-powered and myoelectric

Table 122.5 delineates the advantages and disadvantages of these various options.

Table 122.5. Advantages and Disadvantages of Various Upper-limb Prostheses

Passive Prosthesis

A passive prosthesis can be used for individuals who want nearly life-like cosmesis or who have a high-level amputation and want a lightweight arm for cosmetic reasons. Passive prostheses are lightweight and nonfunctional. Cost depends largely on cosmetic finish. Off-the-shelf cosmetic covers are relatively inexpensive, while nearly life-like silicone covers are expensive.

Body-powered Prosthesis

In a body-powered prosthesis, the components are controlled by gross body movements through a system of straps and a harness that also doubles as a suspension aid. Stainless steel cables are attached to the straps proximally and to parts of the terminal device distally. If the amputation is proximal to the elbow joint, the cable will go through an elbow flexion attachment first. Body movements, such as a shoulder shrug or scapular abduction, put tension on a cable, causing a response. A series of
movements initiates flexion, extension, and locking of the elbow, after which the terminal device can be activated (Table 122.6). If distal, the cables merely control the terminal device. The body-powered prosthesis does not depend on a battery for power, has a quicker component reaction time, and is less expensive than the myoelectric. There is feedback from the cable, and it is more durable and easier to maintain. Conversely, a body-powered prosthesis is at risk for repetitive injury of the activating muscles and joints, has limited pinch-force control for an involuntary terminal device, and can cause irritation to the skin of the contralateral side from the harness.

Myoelectric Prosthesis

Myoelectric prosthetic components are controlled by voluntary muscle action via an electronic signal. The signal is picked up and amplified by electrodes placed over the muscle fibers and then downloaded to a computer to provide a specific function.

To determine whether a patient is a candidate for this type of prosthesis, myoelectric testing is done, before the components are chosen, to determine the maximum threshold available from the muscles. A myoelectric prosthesis provides good cosmesis and does not require a harness to be activated. It has increased range of motion and avoids repetitive-movement injury; it also has increased anatomic function and voluntary wrist rotation. To its disadvantage, a myoelectric device has a slower response time and increased weight distally, as well as higher maintenance. It is battery-dependent and less durable and has a longer down time for repairs. In addition, myoelectric devices are expensive, require longer training, and are less adaptive and not waterproof (Fig. 122.15).

Figure 122.15. Myoelectric prosthesis with a hand attachment shows a battery and electrodes (no socket). (Courtesy of Liberty Technology, Hopkinton, MA.)

Hybrid System

The hybrid system has a combination of body-powered and myoelectric components, such as a body-powered elbow and a myoelectric hand. This combination reduces the weight of the prosthesis and the expense.

Choice of Components

Types of Suspension

The socket design depends on the type of suspension used—suction, bony lock, or harness—and the socket fit.

Full-suction suspension is used for wrist disarticulation and above- or below-elbow amputations. It is more secure, provides greater proprioception, reduces harnessing, and enables pronation and supination where anatomically possible. With full-suction suspension, the prosthesis feels lighter. However, it is more difficult to put on, especially for bilateral amputees, and difficult to fit for short above- or below-elbow limbs. In addition, it may be more expensive than other choices. A suction liner can be used for above- and below-elbow prostheses. It is easier to put on than full suction but may cause skin irritation. However, it is not as secure as full suction and is more expensive.

Bony-lock suspension can be used with or without socks for wrist disarticulation and below-elbow prostheses. It is easy to put on and remove. Its disadvantages are that it can cause muscle atrophy and prevents pronation and supination in below-elbow amputees.

Harness suspension can be used for all upper-extremity prostheses. It is less expensive and more reliable than other suspensions, and the only choice for a shoulder disarticulation or forequarter amputation. The problem is that it is irritating to wear and is less cosmetic.

Terminal Devices

Apart from appearance, weight is a main factor to be considered in the choice of a terminal device. Hooks are lighter, have less of a pendulum effect, and are less tiring to use. One option is to use a hook for daily activities and to attach a hand whenever cosmesis is more important. The passive device is nonfunctional and for cosmesis only. Both the body-powered hook and body-powered hand are voluntary- or involuntary-closing devices. The myoelectric hand is battery-powered and computer-driven. It has specific adaptive equipment, such as for sports, tools, and so forth.

The main groups of wrist units are body-powered and myoelectric. Myoelectric devices can pronate and supinate and are motor-driven. In elbow units, the main groups include passive, body-powered, and myoelectric devices. In shoulder units, there is only a manual unit.

Typical transhumeral and transradial body-powered prostheses are depicted in Figure 122.16 and Figure 122.17.

INTRODUCTION

Cerebrovascular accident (CVA) and traumatic brain injury (TBI) are distinct syndromes: however, the stroke patient and brain-injured patient share many features (1,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32,33,34,35,36,37,38,39,40,41,42,43,44,45,46,47,48,49,50,51,52,53,54,55,56,57,58,59,60,61,62,63,64,65,66,67,68,69,70,71,72,73,74,75,76,77,78,79,80,81,82,83,84,85,86,87,88,89,90,91,92,93,94,95,96,97,98,99,100,101,102,103,104,105,106,107,108,109,110,111,112,113,114,115,116,117,118,119,120,121,122,123,124,125,126,127,128,129,130,131,132,133,134,135,136,137,138,139,140,141,142,143,144,145,146,147,148,149,150,151,152,153,154,155,156,157,158,159,160,161,162,163,164,165,166,167,168,169,170,171,172,173,174,175,176,177,178,179,180,181,182,183,184,185,186,187,188,189,190,191,192,193,194,195,196,197,198,199,200). Both patient groups exhibit upper motoneuron (UMN) syndromes with impairment of motor control, spasticity, and stereotypic patterns of movement (synergy). Cognitive, memory, and sensory deficits are also commonly seen in these patients. Because of the similarities between stroke and TBI, there is a great deal of overlap in terms of specific surgical and nonsurgical techniques for treating the lower extremity problems caused by these conditions.

Lesions of the central nervous system (CNS), the peripheral nervous system, and the musculoskeletal system, as well as lesions causing pain, may lead directly or indirectly to syndromes of restricted or excessive motion of the limbs. Syndromes of restricted limb motion are the most common types of movement impairment. Syndromes of excessive motion are less common. A distinction between restricted versus excessive motion is shown in Table 123.1. The functional implications of each and the treatment of the problems they generate are very different.

| Table 123.1. Clinical Phenomena Associated with Impaired Movement that Functionally Lead to Restricted or Excessive Motion after TBI or CVA

<tr>
<th>Syndrome Type</th>
<th>Associated Movements</th>
</tr>
</thead>
<tbody>
<tr>
<td>Restricted</td>
<td>Voluntary limited</td>
</tr>
<tr>
<td>Excessive</td>
<td>Voluntary increased</td>
</tr>
</tbody>
</table>

Syndromes of restricted limb motion are manifested by impaired access of the limb to targets in the environment during voluntary movement. Limbs are unable or poorly able to move toward objects or places because movement across joints is restricted. An example is a patient with spastic hip and knee flexors who attempts to stand with a crouched posture. Another example seen after head injury is heterotopic bone formation about the hip, which restricts joint motion and impairs use of the lower extremities. The knee may lead to excessive motion and instability during standing.

ORTHOPAEDIC SURGERY AS A REHABILITATION TOOL

The effects of injury to the brain extend beyond the confines of the skull and the subsequent cognitive function of the brain. The musculoskeletal system is profoundly affected by brain dysfunction. Hypertonicity, the unmasking of primitive reflexes and impaired motor control all contribute to the abnormal limb positions, contractures,
and impaired mobility that are so frequently encountered in persons with brain injury.

The converse is also true. The brain is strongly affected by dysfunction of the musculoskeletal system. Just as the hip and knee position of the foot for walking, the musculoskeletal system gives mobility to the brain and positions it to interact with the world. Mobility of the individual is a key element of human life and of fundamental importance to our well-being.

Professionals working in the field of brain injury and stroke rehabilitation are knowledgeable about the cognitive and behavioral deficits that accompany brain injury. It has been our experience that less importance has been given to the musculoskeletal impairment that results from brain trauma or stroke. The penalties of musculoskeletal limitations for the individual can be devastating. Improving an individual’s physical mobility is often therapeutic, leading to increases in cognitive, behavioral, and emotional capacities.

Wellness promotion has become an objective of medical care. This cannot mean the complete prevention of disease, injury, and disability. In the physically disabled population, wellness promotion means maximizing function and mobility in order to avoid the complications of their chronic incapacity. Potential complications of physical immobility include decubiti, infection, pain, social isolation, physical dependence, and emotional dependence. For society, this results in a costly loss of productivity for the patient and often family members as well.

EXPECTATIONS AND TIMING OF ORTHOPAEDIC SURGERY

When evaluating patients with CNS dysfunction, questions commonly arise regarding the indications for surgery, the cost, what outcome to expect, and the practicality of this approach. These issues should be considered on an individual basis for each patient. The following general principles can serve as guidelines for decision making.

1. Operate early, before deformities are severe and fixed. Orthopaedic surgery is a powerful rehabilitation tool. It is often the only treatment that will correct a limb deformity or improve function. Surgery should not be considered a treatment of last resort when “conservative” measures have failed. Physical and occupational therapy cannot effect a permanent change in motor control. Drug therapy for increased muscle tone has generalized effects and cannot be targeted to specific offending muscles. Phenol blocks and botulinum toxin injections provide only temporary modulation of muscle tone. When a permanent treatment is needed to decrease muscle tone or redirect muscle force, consider surgery. The results of surgical intervention are improved when deformities are corrected early. Less muscle lengthening is needed when deformities are mild and there is little or no fixed contracture to overcome. Early surgery preserves maximum muscle strength, joint capsule and ligament flexibility, and articular cartilage integrity. In general, the patient will also be in better physiologic condition to undergo surgery if there has not been a period of several years of immobility.

2. Better underlying motor control means better function for the extremity. Orthopaedic surgery cannot impart control to a muscle. Lengthening a spastic muscle can improve its function by diminishing the overactive stretch response and uncovering any control that is present. Successful surgery depends on a careful evaluation preoperatively to determine the amount of volitional control present in each individual muscle that is affecting limb posture and movement.

Motor performance can be thought of as a continuous scale, with the totally disabled at the lower end and the elite athlete at the upper end. Infinities of small changes in the performance of elite athletes distinguish between the winner and loser. Incremental changes in limb function also result in performance improvements for the disabled individual. Surgery should not be reserved only for patients with severe impairment and deformity. Individuals with milder degrees of impairment can benefit greatly from relatively simple procedures such as lengthening of the Achilles tendon to regain a plantigrade foot for standing, transfers, and ambulation. The amount of improvement correlates best with the degree of underlying motor control and not the severity of the deformity.

3. Distinguish between the function of the extremity and the function of the individual. We commonly speak of “functional” and “nonfunctional” surgical procedures. These terms refer to the expected outcomes for a limb but do not indicate the outcome for the person as a whole. Surgical release of a leg contracted in a flexed and adducted position in a nonambulatory, quadriplegic patient often allows the person to sit comfortably in a wheelchair and become interactive with others.

4. Consider the cost of not correcting limb deformities. The cost of motor control evaluation using dynamic electromyography (EMG) is relatively modest for the benefits it provides. Dynamic EMG is a one-time expense. The cost of performing an incorrect surgical procedure that fails to correct or even worsens a limb deformity is much greater. The cost of performing a surgical procedure is likewise limited when compared with a lifetime of attendant care, spasticity medications, repeated blocks, orthotics to control limb position, complications such as skin ulceration and infection, and lost productivity for the patient and caregivers.

STROKE

Stroke is the leading cause of acquired hemiplegia and long-term disability in the United States (27,86,115,139,142,185,217,227,249). It is also the third leading cause of death. Roughly 600,000 people suffer a new or recurrent stroke each year. Management of the stroke patient has become a major priority for physicians who treat the elderly population. There are 4,000,000 stroke survivors today. The average patient who survives beyond the first few months after a stroke has a life expectancy of more than 6 years (22,82,83). In general, stroke victims survive long enough and achieve adequate function to justify aggressive rehabilitation.

PATHOPHYSIOLOGY OF STROKE

Cerebral function depends on a continuous supply of oxygen. Any significant interruption of oxygenation by thrombosis, emboli, or hemorrhage will result in neuron death and subsequent deficits in cognitive, sensory, and motor functions. Thrombosis is the most common cause of infarction and accounts for nearly three fourths of all CVAs (82,83). Arteriosclerosis is the most significant predisposing factor.

Cranial hemorrhage accounts for approximately one sixth of all CVAs, and includes spontaneous intracerebral hemorrhage and subarachnoid hemorrhage. Hypertension is commonly present in these patients. Isolated cerebral emboli account for less than 10% of CVAs.

Predisposing factors to CVAs include:

- atherosclerosis
- increasing age
- genetic predisposition
- hypertension
- hyperlipidemia
- hypercholesterolemia
- obesity
- cardiac anomalies (arrhythmias, myocardial infarction, hypotension, mural thrombosis)
- diabetes mellitus
- collagen vascular disease (vasculitis, polyarteritis)
- hyperviscosity states (polycythemia, sickle cell anemia)
- tobacco use
- tobacco smoking
- severe cerebrovascular spasm secondary to migraine headaches
- septic vasculitis (tuberculosis, syphilis, and mucormycosis).

NEUROLOGIC IMPAIRMENT FOLLOWING STROKE

Distinct clinical syndromes arise from insults to specific areas of the cerebral cortex. CVAs involving the middle cerebral artery are the most common and produce the typical hemispheric picture of greater impairment in the upper extremity, face, and speech compared with lower extremity involvement. The middle cerebral artery supplies the largest area of cerebral cortex. This area controls sensory and motor function of the trunk, upper extremity, and face, as well as the functions of speech.

The anterior cerebral artery supplies the mid cortex in the sagittal plane. This area of cerebral cortex controls sensory and motor function predominantly in the lower extremity. CVAs involving the anterior cerebral artery result in a hemispheric picture of sensory and motor deficits chiefly involving the lower extremity.

The posterior cerebral artery supplies the visual cortex in the occipital region. Involvement of this artery typically results in visual impairment. Bilateral cortical...
involvement may lead to severe mental impairment, frontal release signs, loss of short-term memory, and inability to learn.

CVAs in the vertebral basilar system are rare. Deficits in balance and coordination arise from interruption of afferent and efferent pathways between the brain and spinal cord. Balance reactions also depend on limb control and proprioception (86, 115, 144, 198).

Cognitive Impairment

Cognitive deficits commonly follow CVAs. Impairment of mentation, decreased learning ability, and loss of short-term memory may occur (12, 16, 22, 25, 33, 42, 50, 60, 82, 83, 93, 104, 106, 144, 151, 160, 161, 164, 179, 217, 226, 251). The ability to cooperate with treatment affects rehabilitation potential. In patients with extensive frontal lobe deficits, these deficits may be severe. Patients with extensive frontal lobe pathology exhibit clinical features similar to those of senility, with lack of attention span and little motivation for recovery. Their prognosis for rehabilitation is poor.

Apraxia is a loss of ability to communicate. It may be receptive or expressive in nature; it usually involves both components. Apraxia occurs with lesions of the left hemisphere, usually without regard to hand dominance. A receptive apraxia hinders rehabilitation most strongly because the patient cannot understand instructions. A patient with persistent receptive loss has a poor prognosis. On the other hand, expressive apraxia may be compatible with rehabilitation, allowing a patient to comprehend and follow instructions. Expressive apraxia may resolve significantly.

Apraxia, or impairment of execution (motor planning), is characterized by a loss of ability to perform a previously learned action, such as tying shoelaces or waving goodbye. Apraxia is not the result of motor or sensory loss. It occurs more commonly with right hemispheric involvement (left hemiparesis). The apraxia, however, occurs on both sides of the body. The prognosis for patients with severe apraxia is generally poor.

Sensory Impairment

A wide span of sensory loss can occur following stroke. Sensory perception occurs in the cerebral cortex and is most often affected by lesions of the middle cerebral artery. Sensory loss may be manifest by impairment of touch, pinprick, two-point discrimination, proprioception, discrimination of size, shape, texture, or point localization, or the presence of asesthesognosia. Impairment of sensory function in the extremities is a poor prognostic sign, even though motor function may be intact or only minimally impaired (4, 12, 16, 22, 25, 26, 27 and 28, 40, 42, 60, 73, 78, 80, 99, 106, 110, 115, 122, 127, 129, 134, 143, 144, 147, 148, 159, 151, 156, 162, 163, 164 and 165, 176, 179, 180, 184, 194, 203, 226, 227, 230, 237, 238, 246, 250, 251). Lesions of the parietal lobe of the nondominant hemisphere may result in a lack of awareness of the involved side of the body (neglect). A failure to recognize and use the involved side may occur despite minimal motor involvement.

Disturbances of vision may occur. These disturbances include hemianopia (blindness in one eye), disturbance of perception, poor perceptual organization, loss of geometric sense, inability to copy figures, and failure to perform tasks involving spatial analysis. Hemianopia is likely to be permanent, but it usually has little impact on rehabilitation potential. Disturbances in visual perception are more significant and may result in failures of activities of daily living (209).

Motor Impairment

Motor impairment is commonly the most obvious sequel of stroke. Recovery follows a fairly typical pattern. A period of flaccid paralysis occurs lasting from 24 hours to several weeks. This is followed by a period of increasing muscle tone. In general, the longer the period of flaccidity, the poorer the prognosis for functional recovery. In the leg, either a flexor or extensor pattern may predominate. With a flexor pattern, the hip and knee are flexed. With an extensor pattern, the hip is adducted and extended, the knee is extended, and the foot is in equinovarus (Table 123.2). These changes are usually evident within 48 hours after the stroke. Any paralysis remaining after 3 months will usually persist, although some slight improvement may occur over a 6-month period (16, 20, 22, 25, 26, 27 and 28, 30, 31, 33, 34, 42, 50, 53, 70, 80, 82, 83, 87, 92, 93, 97, 104, 106, 109, 115, 120, 121, 127, 139, 140, 142, 144, 151, 154, 160, 161, 162, 163 and 164, 179, 180, 181, 184, 187, 194, 196, 202, 215, 216, 217 and 218, 227, 228, 235, 237, 241, 248, 260, 265, 266, 267). Functional improvement may continue as a result of further sensorymotor re-education. Increasing muscle tone usually leads to muscle spasticity. Hyperactive deep tendon reflexes and clonus may appear.

Table 123.2. Common Lower Extremity Limb Deformities

Voluntary movement returns first in the most proximal muscle groups of the limbs and follows in a proximal-to-distal direction or pattern of recovery. Voluntary movement should be sought and examined during the early recovery phase when flaccidity is present.

Grade motor control in the extremity using the clinical scale shown in Table 123.3 (116, 147, 148). The extremity may be hypotonic or flaccid and without any volitional movement. A spastic extremity may be held rigidly without any volitional or reflexive movement. Patterned or synergistic motor control is defined as a mass flexion or extension response involving the entire extremity. Mass flexion in the lower extremity consists of hip and knee flexion with dorsiflexion of the ankle. Mass extension in the lower extremity consists of extension of the hip and knee with equinovarus of the foot and ankle. Synergistic movement may be reflexive and in response to a stimulus but without volitional control. Some patients can also volitionally initiate the synergistic movement. Selective motor control with pattern overlay is defined as the ability to move a single joint or digit with minimal movement in the adjacent joints when performing an activity slowly. Rapid movements or physiologic stress make the mass pattern more pronounced. Selective motor control is the ability to volitionally move a single joint or digit independently of the adjacent joints. Spasticity can mask underlying motor control.

<table>
<thead>
<tr>
<th>Table 123.2. Common Lower Extremity Limb Deformities</th>
</tr>
</thead>
</table>

Patterned movement, even when initiated volitionally, is a primitive form of motor control and of no functional use in the upper extremity. The hand requires some selective control for functional use. The lower extremity can more successfully use synergistic motions for functional activities, such as transfers or walking. For
example, the patient can be taught to use the flexion movement to advance the limb and the extension pattern to provide limb stability during stance.

The final processes in sensory perception occur in the cerebral cortex, where basic sensory information is integrated to complex sensory phenomena such as proprioception, spatial relationships, shape, sight, and texture. A patient with severe parietal dysfunction and sensory loss may lack sufficient perception of space and awareness of the involved segment of his or her body to ambulate. A patient with severe perceptual loss may lack balance to sit, stand, or walk.

ORTHOPAEDIC MANAGEMENT OF STROKE

The Period of Acute Injury

Direct initial efforts toward the medical stabilization of the patient. The orthopaedic surgeon is rarely involved in the acute care of the stroke patient. In some situations, the orthopaedic surgeon may be asked to assist with splinting extremities to prevent limb deformities.

The Period of Physiologic Recovery

Spontaneous neurologic recovery occurs primarily during the first 6 months following a stroke. This is particularly true for recovery of muscle function. During the subacute phase, limb flaccidity changes to spasticity. The patient is commonly in a rehabilitation facility for a portion of this time. Muscle weakness can result in joint subluxation or ligamentous laxity if the limb is not protected. When spasticity becomes pronounced, temporary measures are used to prevent contracture formation until spontaneous neurologic recovery has ceased. It is important to prevent the complications associated with limb spasticity (Table 123.4) (121,122,147,148).

The Period of Functional Adaptation to Residual Deficits

Generally the patient is neurologically stable after 6 months. Decisions can then be made regarding surgery to correct limb deformities and rebalance the muscle forces. This is the time of greatest contribution by the orthopaedic surgeon.

TRAUMATIC BRAIN INJURY

Injury to the brain is a leading cause of disability and death in the United States (68,99,100,141,165,209,211,219,224,258). An epidemiologic study of physician-documented cases of TBIs occurring in San Diego County, California, in 1981 determined an annual incidence of 180 per 100,000 population (141).

Extrapolating this rate to the entire United States population provides an estimate of 410,000 new cases of TBI cases each year. Eleven percent of these patients will die shortly after the injury. Approximately 80% of the survivors will have a good or moderate neurologic recovery. Most traumatic injuries to the brain are in individuals who are younger than 45 years of age, and those who survive have a normal life span despite the injury.

PROGNOSIS

Prognosis following TBI has traditionally been predicted relative to the Glasgow Coma Scale (GSC) (Table 123.5) (99,100,219). The GCS is the total of the scores of a patient’s responses to eye opening, motor responses, and verbal responses. Obtained within 24 hours of the patient’s admission to the hospital, a GCS of 11 or greater is associated with an 82% probability of moderate or good neurologic recovery. Lower scores have a significantly higher incidence of severe sequelae. The Glasgow Outcome Scale (Table 123.6) is frequently used to grade long-term recovery following TBI.

Age is an important factor in neurologic outcome following brain injury regardless of the severity of injury. As a group, patients younger than 20 years of age at the time
of brain injury experience a 62% chance of moderate or good neurologic recovery. Patients between 20 and 30 years of age can expect a 46% chance of moderate or good neurologic recovery. In a series of pediatric patients with brain injury, overall 90% achieved a moderate or good neurologic recovery and only 8% expired or remained in a persistent vegetative state (95,96). Young children with a GCS of 5 or better have a good prognosis for recovery. In addition to having a poorer prognosis for recovery, the cost and time required for rehabilitation of older patients is higher than that for younger patients (49).

Although the GCS has been demonstrated to predict mortality accurately, recent studies have suggested the GCS as a single variable may have limited value as a predictor of functional outcome, and many trauma centers are now using the Revised Trauma Score (RTS) to assist with triage of multitrauma patients. The RTS combines the GCS with the systolic blood pressure and respiratory rate, and is used to predict both mortality and disability (65,489).

The duration of coma is another prognostic indicator. If emersion from coma occurs within the first 2 weeks of brain injury, 70% of patients can be expected to achieve a good recovery. If the coma persists beyond 4 weeks, the chance of good recovery is much diminished. Brain stem involvement, as indicated by the presence of decerebrate or decorticate posturing, has a poor prognosis for outcome. If decerebrate posturing occurs and resolves within the first week after injury, 40% of patients will receive a good neurologic recovery. If decerebrate posturing persists beyond the first week, only 9% of patients will achieve a good neurologic recovery. In a similar manner, the duration of posttraumatic confusion can also be an indicator of prognosis. If the period of posttraumatic confusion persists for more than 4 weeks, one third of patients will have a poor neurologic outcome. It should be remembered, however, that prognosis is a probability statement, and although various factors can be used as guidelines, none is an absolute indicator in the individual patient.

ORTHOPAEDIC MANAGEMENT OF BRAIN INJURY

The orthopaedic management of TBI can be divided in three distinct time periods (73,78,122,147,148):

- the period of acute injury
- the period of physiologic recovery
- the period of functional adaptation to residual deficits

The Period of Acute Injury

The initial phase of management occurs immediately following the injury in the acute care hospital. The majority of TBIs are the result of a motor vehicle accident. Multiple trauma is common. The orthopaedic surgeon is a consultant with a critical role. Aggressive treatment of orthopaedic injuries at an early stage is important to functional outcome.

The first priority is to diagnose all injuries accurately (1,8,21,23,36,58,61,63,68,71,73,76,85,98,113,145,166,168,186,188,189,204,205,209,210 and 211,253,255). It is common for injuries such as fractures or major peripheral nerve injuries to go undetected. Garland reported an 11% incidence of delayed diagnosis of fractures, with an average time to diagnosis of 57 days (68.209). In the comatose patient, obtain radiographs of all major joints and any other areas suspected of injury. It is important not to assume that all neurologic deficits present are from the CNS injury. Stone and Keenan (209) reported that 34% of brain-injured patients have missed peripheral nerve injuries. Especially in the presence of a limb fracture, suspect a peripheral nerve injury (68.209).

After head injury, pain is often caused by reflex sympathetic dystrophy, deep vein thrombophlebitis, spasticity, occult fracture, and the formation of heterotopic ossification (HO) (37,63,84,85,166,204,209,210-223). If pain is treated promptly (and this depends on accurate and early diagnosis), prolonged restriction of motion may be prevented. HO, fracture, and fracture malunion restrict motion due to lost structural integrity. Many brain-injured patients who recover cognitive function have residual spasticity and impaired balance, and consequently, are less able to compensate for such structural impediments (63,156). Peripheral nerve injury produces weakness and pain, both possible causes of restricted motion.

The second rule of orthopaedic care is to assume that the patient will make a good neurologic recovery. Treat all orthopaedic injuries promptly and appropriately. When possible, internal fixation is best. Spasticity develops, and casting a spastic joint in a flexed position may result in a joint contracture or an unsatisfactory reduction. Fracture healing is accelerated, presumably by the same humoral factors that contribute to heterotopic bone formation (10,111,190,222). Fracture malunion is a common and potentially avoidable complication (Fig. 123.1).

The third principle is to expect lack of patient cooperation. The patient emerging from coma may go through a period of agitation and confusion. Fracture care should be made as foolproof as possible because patient cooperation cannot be expected. In anticipating a possible period of agitation, avoid, where possible, traction and external fixators for treatment of extremity fractures (63,71,73,76,81,196-224,243,253).

The Period of Physiologic Recovery

Following TBI, neurologic recovery can proceed for a prolonged period of time. The majority of improvement in motor control occurs within the first 6 months following injury. Cognitive improvement occurs most rapidly in the early phases following brain injury but can continue for a very prolonged period of time, often years (Table. 123.7) (66). Because the period of potential neurologic recovery following head injury is prolonged, definitive surgical procedures are avoided during the transitional stage. There is no exact time that must elapse before considering surgery to improve musculoskeletal function. Consider the rate of continued improvement in motor control when deciding at what point to intervene surgically. If the additional improvement in motor control will be overridden by the complications of contracture formation, osteopenia, peripheral nerve compression, and muscle atrophy, then early surgical intervention is appropriate.

Table 123.7. Rancho Levels of Cognitive Functioning
During the period of physiologic recovery, the patient is commonly left with residual limb deformities from spasticity, contractures, and muscle imbalance. At this time that definitive orthopaedic surgical procedures are performed to rebalance the muscles and correct the residual deformities.

HETEROTROPOUS OSSIFICATION

HO presents clinically with an intense inflammatory reaction about the joint seen as redness, warmth, severe pain, and rapidly decreasing range of motion (5, 13, 18, 36, 37, 39, 41, 44, 47, 48, 54, 56, 61, 62, 63, 64 and 65, 67, 69, 72, 73, 77, 86, 98, 111, 113, 128, 135, 149, 153, 157, 169, 173, 188, 190, 222). An other common complication of spasticity is heterotopic bone formation posterior to the hip joint. In some cases, the bone can encase the sciatic nerve. During the period of physiologic recovery, the temporary control of spasticity is the major focus of treatment. Prevention of the heterotopic bone formation is critical to a good functional outcome (5, 13, 18, 36, 37, 39, 41, 44, 47, 48, 54, 56, 61, 62, 63, 64 and 65, 67, 69, 72, 73, 77, 86, 98, 111, 113, 128, 135, 149, 153, 157, 169, 173, 188, 190, 191 and 192, 199, 204, 205, 206 and 207, 209, 210, 212, 213, 222, 223, 243, 245, 253, 256, 257). Early joint contractures are also best corrected during this phase of treatment. This is accomplished by first reducing spasticity and then correcting contractures by splinting, casting, and range-of-motion therapy.

Figure 123.2. Radiograph of a hip showing periarthritis heterotopiac ossification posterior and lateral to the joint.

The Period of Functional Adaptation to Residual Deficits

When physiologic neurologic recovery has ceased, the brain-injured patient is commonly left with residual limb deformities from spasticity, contractures, and muscle imbalance. At this time that definitive orthopaedic surgical procedures are performed to rebalance the muscles and correct the residual deformities.

REFLEX SYMPTOMATIC DYSTROPHY

Reflex sympathetic dystrophy (RSD) is characterized by "constant, spontaneous, severe, burning pain and is usually associated with hypo- and hyperesthesia, hyperpathia, and allodynia, along with vasomotor and sudomotor disturbances that, if persistent, result in trophic changes" (65). RSD commonly develops following CVI (posthemiplegic dystrophy), TBI, and surgery. It may be associated with trauma that occurred concurrently with TBI, although the severity of the initial injury is unrelated to the severity of the ensuing symptoms.

Onset following trauma is usually within the first several weeks; however, with stroke and brain injury, the onset may be delayed and atypical. Because of this, RSD may remain undiagnosed in the stroke or brain-injured patient until it becomes irreversible.

Radiographs showing patchy demineralization of involved epiphyses even during the first phase suggest the diagnosis. Subperiosteal resorption, tunneling of the cortex, and striation may be evident on good-quality films. Unfortunately, none of these changes are specific for RSD. A triple-phase bone scan may help with diagnosis. The pattern seen varies with the phase of the disease. In the acute phase, the flow (immediate), blood pool (early), and delayed (static) scan patterns show increased uptake, usually in a periarticular distribution. False-negative results are frequent in the dystrophic phase, in which the flow and blood pool scans are normal, and the delayed scan shows a somewhat less prominent periarticular increase in uptake. In the atrophic phase, both the flow and early scans show decreased uptake, whereas the delayed phase is normal.

Treatment includes several modalities. Physical therapy, particularly active and active assisted range of motion, gentle muscle strengthening and conditioning, massage, and heat therapy have been effective. Tricyclic antidepressants (amitriptyline) may have an effect because of their inhibition of serotonin uptake at pain-suppressing neurons, prolonging the serotonin effect at the receptor. Narcotics have a role in low-dose epidural infusions in combination with local anesthetics. Systemic corticosteroids and adrenergic blocking agents have both been advocated. Use of nerve blocks, including stellate ganglion blocks, Bier blocks, surgical sympathectomy, and chemical sympathectomy, have been reported resulting in improvement in a high percentage of patients. At present, we use a regimen of amitriptyline, physical therapy, and percutaneous sympathetic blockade.

GENERAL CONSIDERATIONS FOR DECISION MAKING

DEGREE OF SPASTICITY

Multiple complications can occur in the presence of spasticity (see Table 123.4). Contractures are common. Limited positioning and myostatic contractures combined with the patients diminished nutritional status can result in pressure sores or hygiene problems. When fractures are present, malunions can occur in the face of uncontrolled muscle tone and accelerated fracture healing. Joint subluxation can also occur from prolonged spasticity or the attempts to range a joint in the face of severe spasticity. If a ligamentous injury occurred at the time of injury, frank dislocation of a joint can be caused by hyper trickony. Spasticity also appears to be one of several etiologic factors in the formation of HO in periarticular location (Fig. 123.2) (13, 18, 41, 44, 62, 63, 64 and 65, 67, 69, 72, 73, 86, 98, 111, 113, 128, 135, 149, 153, 157, 159, 169, 173, 188, 190, 222). An other common complication of spasticity is acquired peripheral neuropathy (36, 47, 51, 61, 68, 166, 209). The most common peripheral neuropathies acquired with severe spasticity and contracture formation are ulnar neuropathy at the elbow from severe flexion and control pressure on the ulnar nerve and carpal tunnel syndrome secondary to severe wrist flexion and pressure of the median nerve against the leading edge of the transverse carpal ligament (165). In the lower extremity, sciatic neuropathy can result from trauma such as a hip dislocation or acetabular fracture. Sciatic neuropathy can be caused by the pronounced inflammation associated with heterotopic bone formation posterior to the hip joint. In some cases, the bone can encase the sciatic nerve. During the period of physiologic recovery, the temporary control of spasticity is the major focus of treatment. Prevention of additional complications, such as disuse muscle atrophy, joint contractures, HO, and peripheral neuropathies, is critical to a good functional outcome (5, 13, 18, 36, 37, 39, 41, 44, 47, 48, 54, 56, 61, 62, 63, 64 and 65, 67, 69, 72, 73, 77, 86, 98, 111, 113, 128, 135, 149, 153, 157, 159, 173, 174, 181, 185, 188, 190, 191 and 192, 199, 204, 205, 206 and 207, 209, 210, 212, 213, 222, 223, 243, 245, 253, 256, 257). Early joint contractures are also best corrected during this phase of treatment. This is accomplished by first reducing spasticity and then correcting contractures by splinting, casting, and range-of-motion therapy.

DEGREE OF SPASTICITY
The majority of stroke patients have a period of limb flaccidity before the gradual onset of increasing muscle tone or spasticity (resistance to quick stretch). Because these patients are generally older than brain-injured patients, their muscles are also weaker. This, combined with the shorter period of spontaneous neurologic recovery (6 months), makes the temporary control of spasticity an easier task in stroke patients. The use of phenol nerve blocks or intramuscular botulinum toxin injection is therefore less common than in the TBI patient.

**TIMING OF NEUROLOGIC RECOVERY**

The prolonged period of physiologic recovery, the intense level of spasticity (response to fast stretch), the presence of rigidity (resistance to slow stretch), and the strong muscles found in young TBI patients make the temporary control of spasticity much more difficult. Phenol nerve blocks, botulinum toxin injections, and casting are used more commonly and aggressively.

**PATTERN OF NEUROLOGIC RECOVERY**

The majority of stroke patients (middle cerebral artery infarcts) have hemiplegic involvement with a nonfunctional upper extremity and a lower extremity with greater potential for function. The surgical procedures used to correct residual deformities in the upper extremity are more likely to be for the correction of contractual deformities than to improve function. Even when functional procedures are employed, the gains from these procedures are more modest than those in the brain-injured patient.

In contrast, the young brain-injured patient is more likely to have quadriplegic involvement, concomitant peripheral nerve injuries, residual deformities from fractures, and joint limitation from HO but better return of motor control. Functional surgical procedures are more common in these patients.

**TEMPORARY MANAGEMENT OF SPASTICITY DURING THE PERIOD OF PHYSIOLOGIC RECOVERY**

The treatment of spasticity depends on the time since injury and the prognosis for further recovery. In the period of physiologic recovery, temporizing interventions are used because permanent changes may result in chronic imbalance of forces across joints (14,15,17,29,46,52,73,74 and 75,102,104,107,118,119,131,132 and 133,155,158,197,202,225,247,249). Prevention of additional complications, such as disuse muscle atrophy, joint contractures, HO, and peripheral neuropathies, is critical to a good functional outcome. Several choices are available for treatment.

A combination of peripheral nerve blocks and casting or splinting techniques are commonly used to give temporary relief of spasticity. Casting maintains muscle fiber length and diminishes muscle tone by decreasing sensory input (14,73). Local anesthetic nerve blocks are very helpful when they are administered before cast application because relieving the spasticity allows for easier limb positioning (63a,123,3). Casts are used primarily for the correction of contractual deformities by applying a cast on a weekly basis. Serial casting is most successful when a contracture has been present for less than 6 months.

**PHENOL BLOCKS**

Phenol, a derivative of benzene, in aqueous concentrations of 5% or more denatures the protein membrane of peripheral nerves. When phenol is injected in or near a nerve bundle, its neurolytic action on the myelin sheath or the cell membranes of axons with which it makes contact serves to reduce neural traffic along the nerve. The onset of the destructive process with higher concentrations of phenol may begin to show effects several days after injection. The denaturing process induced by phenol extends biologically on the order of weeks but eventually regeneration occurs. A phenol block is used as a temporizing measure rather than a permanent intervention. In our clinical experience and the experience of others, the effect of a phenol block typically lasts 3 to 5 months (15,17,29,46,73,74 and 75,101,102,104,107,118,119,131,132 and 133,155,158,225,249). These agents are used when restricted motion occurs as a result of focal spasticity. When these agents “wear off,” the patient is re-evaluated to determine whether additional recovery has taken place and whether there is further indication for reblocking. It is critical that the functional problems of the patient be accurately ascribed to specific muscles. This is done by evaluation using multichannel dynamic EMG (60,105,109,112,117,125,136,137,147,148,176,183). Even if many muscles in a limb are involved, a number of focal injections are possible, and by doing so, CNS side effects can be avoided. For patients with pathologies causing excessive motion, environmental modification weights, bracing, and oral medications may be considered during the period of physiologic recovery.

**Figure 123.3.** The most commonly performed local anesthetic nerve blocks in the lower extremity. (From Keenan MAE. The Orthopaedic Treatment of Spasticity. The Journal of Head Trauma Rehabilitation 1987;2:62.)

Oral antispastic agents may be used during this period. Antispastic agents that have sedating properties, such as baclofen, diazepam, and clonidine, may compromise patients with attention deficits or memory disorders. Even a drug such as dantrolene sodium, which has a peripheral mechanism of action, may also cause drowsiness. Other serious side effects such as hepatotoxicity can occur. Continuous infusion of intrathecal baclofen has been reported to be useful in managing spasticity secondary to spinal cord injury. Such delivery avoids the cognitive side effects seen with oral delivery. Early studies have shown that intrathecal bolus infusions of baclofen via a catheter placed in the lumbar space may also be capable of reducing spastic hypertonia associated with brain injury (3,152).

Focal injection with neurolytic or chemodenervating agents is the most suitable approach for treating restricted motion secondary to spasticity. Neurolytic agents such as phenol and chemodenervation agents such as botulinum toxin A are used during this period because their effects are temporary, lasting only 3 to 5 months (15,17,29,46,73,74 and 75,101,102,104,107,118,119,131,132 and 133,155,158,225,249). These agents are used when restricted motion occurs as a result of focal spasticity. When these agents “wear off,” the patient is re-evaluated to determine whether additional recovery has taken place and whether there is further indication for reblocking. It is critical that the functional problems of the patient be accurately ascribed to specific muscles. This is done by evaluation using multichannel dynamic EMG (60,105,109,112,117,125,136,137,147,148,176,183). Even if many muscles in a limb are involved, a number of focal injections are possible, and by doing so, CNS side effects can be avoided. For patients with pathologies causing excessive motion, environmental modification weights, bracing, and oral medications may be considered during the period of physiologic recovery.

**BOTULINUM TOXIN BLOCKS**

Botulinum toxin is a newer agent used in the localized treatment of spasticity. Ordinarily, an action potential propagating along a motor nerve to the neuromuscular junction triggers the release of acetylcholine (ACh) into the synaptic space. The released ACh causes depolarization of the muscle membrane, activating a biochemical sequence that leads to muscle contraction. Botulinum toxin type A is a protein produced by *Clostridium botulinum* that inhibits this calcium-mediated release of ACh at the neuromuscular junction. Botulinum toxin A attaches to the presynaptic nerve terminal and divides into a light and a heavy component. The light component gets into
Botulinum toxin injection has been used to treat a variety of dystonias and has been approved by the U.S. Food and Drug Administration for the treatment of blepharospasm, facial spasm, and strabismus. A number of studies have reported its use in treating spasticity in individuals with cerebral palsy, stroke, head trauma, and multiple sclerosis (16,52,60,147,148,197,202,247). The clinical benefit lasts 3 to 5 months but may be more variable. Botulinum toxin is injected directly into an offending muscle and, depending on the size of the muscle being injected, dosing has ranged between 10 and 200 units (U). Current practice is to wait at least 12 weeks before reinjection and not to administer a total of more than 400 U in a single treatment session. Because this upper limit of 400 U may be reached rather quickly, a different strategy is needed for the limb requiring many proximal and distal injections. Botulinum toxin A and phenol may be combined, with botulinum toxin A being injected into smaller distal muscles and phenol aimed at larger proximal ones. A 3- to 7-day delay between injection of botulinum toxin A and the onset of clinical effect is typical. Effects are not seen immediately by the patient, and usually a follow-up visit is arranged to check the result. The amount of toxin given for a particular muscle is variable.

The technique of botulinum toxin injection varies. Some physicians inject through a syringe attached to a hypodermic needle that doubles as a monopolar EMG-recording electrode. Patients may be asked to make an effort to contract the targeted muscle, or the muscle may contract involuntarily as in dystonia. After inserting the needle electrode, injection is made when EMG activity is recorded. For deep or small spastic muscles (e.g., extrinsic toe flexors), electrical stimulation is preferred to localize the muscle before injection.

Botulinum toxin injections have gained much popularity in the past several years. The advantages of botulinum toxin are its ease of injection and the lack of residual scarring after injection. The disadvantages of botulinum toxin are its high cost and the stimulation of antibody formation, which requires higher doses for repeated injections. Phenol, by contrast, requires more technical expertise to localize the nerve or motor points for injection. Phenol is caustic and causes localized scarring of the nerve and muscle. On the other hand, phenol is inexpensive and readily available.

### COMMON TECHNIQUES OF NERVE AND MOTOR POINT BLOCKS

#### Hip Adductor Spasticity

Severe spasticity of the hip adductor muscles causes multiple problems (73,78,103,122,127,147,148,155,158,176,179,184,226). These include limited access to the perineum resulting in poor hygiene, limited positioning of the patient, and the formation of decubitus ulcers. In more functional patients, the increased adductor tone causes scissoring of the legs when the patient is upright. Scissoring interferes with balance, transfers, and ambulation by narrowing the base of support (Fig. 123.4).

![Figure 123.4. Limb scissoring caused by spasticity of the hip adductor muscles produces a narrow base of support and difficulty with balance during ambulation.](image)

There are several techniques for controlling spasticity on a temporary basis in a patient who is still in the period of physiologic recovery (Table 123.8). A phenol block of the obturator nerve can be performed percutaneously to decrease the hip adductor tone. Because the sensory component of the obturator nerve is small, direct injection of the nerve is not problematic. It is advisable to administer an anesthetic nerve block first to rule out a myostatic contracture. Locate the obturator nerve as it emerges from the obturator canal by using a nerve stimulator and insulated needle electrode. Then inject 2 to 5 ml of 5% phenol in saline. The block will gradually take effect over the following 24 hours, and the effects will last for approximately 2 months. While the hip adductor tone is decreased, use gentle range of motion exercises to stretch out any contracture. Transfer and gait training can be continued.

**Table 123.8. Techniques for the Temporary Management of Spasticity**

Botulinum toxin injections of the hip adductor muscles can also be administered. If many large muscles in the lower extremity require treatment for control of spasticity, phenol is a more practical choice.

#### Hip Flexor Spasticity

Severe spasticity of the hip flexor muscles not only causes hip flexion contractures but may also contribute to knee flexion deformities (Fig. 123.5). When hip flexor spasticity cannot be controlled by the use of a long-leg cast, prone lying, or positioning devices, then percutaneous paraspinal blocks of the upper lumbar nerve roots can be performed to diminish hip flexor spasticity.

![Figure 123.5. Patient with severe, longstanding flexion contractures of both the hips and knees. The patient developed multiple pressure sores and had a flap](image)
Localize the nerve roots by using an insulated spinal needle and nerve stimulator. Then inject 1 to 2 ml of 5% phenol in saline. The hip flexor tone can be expected to decrease gradually over the following 24 hours. Then begin a physical therapy program to stretch out any fixed hip flexion contracture.

Botulinum toxin injections of the hip flexor muscles can be administered but are technically difficult given the deep location of the muscles and the proximity of the large femoral vessels.

**Hip Extensor Spasticity**

Severe spasticity of the hip extensor muscles can occur with a brain stem or anoxic injury. Lack of adequate hip flexion range of movement will greatly interfere with a patient's ability to sit in a chair ([Fig. 123.6](#)). Siting is a crucial step in rehabilitation because it allows a person to begin interacting with people and objects in the environment.

![Figure 123.6. Spasticity of the hip and knee extensor muscles in a brain-injured patient results in difficulty while sitting. This young patient requires the use of a seat belt and a semireclining wheelchair to maintain her position.](#)

Percutaneous phenol injection of the inferior gluteal nerve as it enters the muscle belly of the gluteus maximus is an effective technique in reducing hip extensor tone and maintaining the ability to flex the hip. The inferior gluteal nerve enters the gluteus maximus muscle at the center of the muscle belly just proximal to the piriformis tendon. Carefully localize the nerve with an electrode needle and a nerve stimulator before injection. Inject 2 ml of 5% phenol in saline into the muscle at the motor point. The muscle tone can be expected to diminish over the following 24 hours. Then begin passive range-of-motion exercises to increase hip flexion range. A continuous passive motion machine is helpful to supplement the physical therapy program. Botulinum toxin injections of the hip extensor muscles can also be administered.

**Knee Flexor Spasticity**

When severe hamstring spasticity is present, knee flexor contractures develop very rapidly ([Fig. 123.5](#)). Because of the large sensory component of the sciatic nerve, direct injection with phenol is undesirable. The dissection required to identify the multiple motor branches of the hamstring muscles is extensive and often impractical. Phenol motor point injections or botulinum toxin injections of the hamstring muscles can be administered. Prevention of knee flexion contractures can also be achieved by performing repeated anesthetic nerve blocks of the sciatic nerve and casting the limb in extension ([73,78,80,88,101,103,120,122,127,147,149,169,174,178,194,201](#)). Take care to observe the knee very closely during the casting program to avoid posterior subluxation of the knee joint. Using a sciatic nerve block at the time of casting diminishes the likelihood of this complication. An anesthetic block of the sciatic nerve will also temporarily eliminate calf spasticity and allow for serial casting of an equinus contracture of the foot, if present.

When serial casting and sciatic nerve blocks fail to correct a knee flexion deformity or when posterior subluxation of the tibia occurs secondary to the hamstring tightness, a lengthening of the hamstring muscles can be performed even in the early stages following injury. The biceps femoris, gracilis, and the semimembranosus muscles have myotendinous junctions that permit a fractional lengthening. The semitendinosus muscle is either divided or lengthened ([Fig. 123.7](#)). Casting is still commonly needed following hamstring lengthening to correct the residual flexion deformity.

![Figure 123.7. Lengthening of the biceps femoris, semimembranosus, and gracilis muscles at the musculotendinous junction. The semitendinosus is released.](#)

**Knee Extensor Spasticity**

Severe spasticity of the quadriceps muscles may be seen in brain stem injuries or anoxic brain damage ([Fig. 123.8](#)). When knee range of motion cannot be maintained because of quadriceps tone, a percutaneous phenol block of the femoral nerve can be performed ([15,38,46,60,73,101,102,131,132,147,149,155,158,247,249](#)). This block, in combination with the use of a continuous passive motion machine, is then used to regain and maintain adequate knee range of motion. Even in a severely injured patient, knee and hip flexion range should be preserved to permit adequate sitting in a chair.

The femoral nerve has a minimal sensory component and can therefore be directly injected using a percutaneous technique. Localize the nerve in the groin lateral to the femoral vessels by using an electrode needle and nerve stimulator. Then inject 2 ml of 5% phenol in saline. Relaxation of quadriceps muscle tone can be expected to last 2 to 3 months. Use physical therapy and continuous passive motion to regain knee flexion range.

It is also possible to locate the motor points of the individual muscles of the quadriceps and perform motor point blocks using phenol. Use a surface stimulator to find the general vicinity where the motor branches of the femoral nerve enter each muscle belly. These are located at the proximal end of the muscles. Then use a needle electrode and stimulator to localize the motor nerve more accurately.

Botulinum toxin injections of the knee extensor muscles can also be administered. Because the quadriceps are large muscles, a large volume of botulinum toxin would be needed. It would also require injections to be given on several occasions. For these reasons, phenol is a more practical choice.
Ankle Plantarflexor Spasticity

Excessive spasticity of the gastrocnemius and soleus muscles causing equinus posturing of the foot is very common. When the spasticity is mild, it can generally be contained and an equinus contracture prevented by using a rigid ankle-foot orthosis (AFO). At times the muscle tone is too severe to be adequately controlled by a brace. The patient may exhibit ankle clonus while in the upright position, causing the foot to piston up and down in the brace.

Some rehabilitation specialists do percutaneous phenol injections of the posterior tibial nerve. We do not recommend this procedure because of the large sensory component of the nerve. Phenol is a caustic substance, and its injection into a mixed nerve can result in severe painful dysesthesia and loss of sensation on the plantar aspect of the foot. A phenol block of the motor branches of the posterior tibial nerve can be performed as a surgical procedure to preserve sensation to the plantar aspect of the foot (Fig. 123.8) (73,75,78,103,108,122,127,147,148).

- Make an incision on the posterior aspect of the calf at the midline beginning just distal to the popliteal crease.
- Identify the posterior tibial nerve between the heads of the gastrocnemius muscle and trace it distally. Use a nerve stimulator to identify the motor branches. When all of the motor branches have been identified to the gastrocnemius, soleus, posterior tibialis, flexor hallucis longus, and flexor digitorum muscles, protect each from the surrounding tissue with a moistened gauze sponge.
- Then inject the motor branches with a 5% phenol solution in glycerin. Glycerin is used for surgical phenol blocks because it allows the phenol to be released more slowly and therefore prolongs the effect of the block for 6 months. The glycerin solution is too viscous for percutaneous use.

Postoperatively, protect the patient with an AFO to maintain the ankle at a neutral position to protect the calf muscles while the block is in effect.

Since the advent of botulinum toxin injections, surgical phenol blocks of the posterior tibial nerve are rarely needed. It is much more practical to inject the gastrocnemius and soleus muscles with botulinum toxin. It is usually necessary to inject the flexor hallucis and flexor digitorum muscles simultaneously because they both contribute to the equinus. Use an AFO after botulinum toxin injections because of the muscle weakness caused by the blocks.

Ankle Invertor and Evertor Spasticity

Spasticity of the tibialis anterior muscle has been shown to be a primary muscle responsible for the varus deformity of the foot in both stroke and brain-injured patients (Figs. 123.9 and Figs. 123.10) (16,20,22,25,26,28,43,49,60,78,80,103,105,106,108,109,122,127,138,147,148,163,174,175,176,177 and 178,180,184,194,195,226,227,230,241). Most frequently, this deformity can be controlled initially with the use of an AFO. In the event that a brace does not control the foot, a phenol block of the motor branch of the deep peroneal nerve in the proximal leg can be performed percutaneously to decrease the spasticity. Localize the nerve by using a stimulator and needle electrode before injection with 1 ml of 5% phenol in saline. Alternatively, inject the muscle with botulinum toxin. The extensor hallucis longus (EHL) muscle and the tibialis posterior muscle can significantly contribute to a varus foot deformity. Phenol motor point or botulinum toxin injections of these muscles are often needed as well. Use an AFO to maintain a neutral foot position after the blocks.

Figure 123.9. Patient with a spastic equinovarus deformity of the foot following a cerebrovascular accident.

Figure 123.10. Dynamic electromyogram (EMG) obtained during walking from a stroke patient with a spastic equinovarus foot deformity. The foot switches on the baseline indicate the swinging and stance phases of gait. The tibialis anterior shows continuous activity in a nonphasic manner throughout (class IV EMG activity; see Table 123.9). The gastrocnemius shows class II EMG activity, which begins prematurely during the late swing phase and continues throughout the stance phase. The soleus muscle also shows class II activity with premature firing in late swing, continuing throughout the stance phase. The flexor hallucis longus exhibits class IIIC activity. The activity is continuous, but some phasic element can be seen with increased amplitude in midstance.
Although less common, spastic valgus foot deformities can occur. Phenol motor point or botulinum toxin injections of the offending peroneal muscles temporarily control the deformity.

**EVALUATION OF RESIDUAL LIMB DEFORMITIES**

**ASSESSMENT OF COGNITION AND COMMUNICATION**

Extremity function requires that complex and highly sophisticated mechanisms work together in unison. Improving lower extremity function requires careful systematic evaluation before surgery. The goals of surgery must be practical and clearly understood by the patient and the family. Assessment includes an evaluation of cognition and communication skills (1,20,22,25,29,78,80,101,105,106,109,115,122,138,147,148,150,151,156,178,184,194,195,228,241). This is done during the physical examination. The patient must be capable of following simple commands and should also be able to cooperate with a postoperative therapy program. In addition, the patient should have sufficient cognition to incorporate the improved motor function into their use of the extremity. Adequate memory is needed to retain what is taught during postoperative therapy.

**SENSORY EVALUATION**

The ability to maintain balance and ambulate depends on adequate sensation in the foot and ankle. The basic modalities of light touch and pain sensation are essential. Proprioception must be present at the level of the ankle joint for good balance reactions. If proprioception is impaired at the ankle, an AFO may be needed during ambulation to prevent a compensatory knee extension thrust (115,175,178,180).

**EVALUATION OF LIMB DEFORMITY AND POTENTIAL FUNCTIONAL CAPABILITY**

Diffuse axonal injury, multifocal vascular pathology, and diffuse hypoxic encephalopathy lead to a large variety of posttraumatic motor phenomena, many of which are functionally significant. Lesions affecting the corticospinal system, the cerebellum and its pathways, and the extrapyramidal system are common. Hemiparesis is the most common long-term residual of head injury. Many patients, however, have a brain stem syndrome consisting of spasmodal ataxia and contralateral spastic hemiparesis. A small percentage have a pseudobulbar athetoid type of picture. Patients can also have residuals of bilateral hemiparesis, ataxia involving both sides of the body, and severe dystonic de cerebrate posture or rigidity. Many patients, especially during the early recovery stage from head injury, reveal mixed signs such as spasticity combined with tremor and ataxia. Pronounced although unusual, is also seen. Because so many different aspects of the motor control system may be affected by a head injury, we present a way of organizing the unwieldy array of symptoms that emerge from a damaged nervous system (147,148). Our perspective is a practical one, namely taking into account the impact of movement disorders on the patient's ability to function in real life.

Treatment of spasticity is most effective when functional problems are formulated and described in focal rather than diffuse terms. Treatment of focal problems lends itself well to surgical intervention, which can target particular muscles. Surgical lengthening, transfer, or release of targeted muscles can provide very effective solutions to problems of function that are clearly identified from the outset. The localizing approach is useful because it forces the clinician to indicate the desired outcome in advance. The outcome is based on an analysis that identifies the specific spastic muscles responsible for the problem. For example, if the clinical problem is an equinovarus foot that inhibits walking, surgically lengthening or transferring the tibialis posterior will not solve the problem if tibialis anterior and gastrocsoleus muscles are really the culprits responsible for the problem. Identifying the specific offending muscles is critically important to localized strategies of intervention (59,101,105,129,175,176) and (177,179,180,231,232,241).

In a neurologically impaired patient, it is frequently difficult to distinguish between the many potential causes of limited joint motion. The possibilities include increased muscle tone, a myostatic contracture, the presence of periarticular HO, an undetected fracture or dislocation, joint subluxation, pain, or the lack of patient cooperation secondary to diminished cognition. Bony deformities may not exhibit an obvious clinical deformity but can be detected by radiography.

**Clinical Evaluation of Motor Control**

Evaluation of spasticity focuses on identification of three factors: (1) the clinical pattern of motor dysfunction, (2) the patient's ability to control muscles involved in the clinical pattern, and (3) the role of muscle stiffness and contracture in relation to the functional problem. For purposes of convenience, we identify seven clinical patterns of lower extremity motor dysfunction that are most commonly seen (Table 123.2).

Other variations of motor dysfunction occur but are less common. Various muscles may contribute to motor dysfunction across joints and limb segments in these clinical patterns. Evaluation focuses on the following characteristics of the involved muscles: voluntary or selective control, spastic reactivity, rheologic stiffness, and contracture. Ask five specific questions:

- Does the patient have voluntary control over a given muscle?
- Is the muscle spastic to passive stretch?
- Is the muscle, as an antagonist, activated during active movement generated by an agonist?
- Does the muscle have increased stiffness when stretched?
- Does the muscle have fixed shortening (contracture)?

When many muscles cross a joint, the characteristics of each muscle may vary. Because each muscle may contribute to motion and movement of the joint, information about each muscle's contribution is useful to the assessment as a whole. Treatment depends on such information (65,147,148).

Spasticity often masks underlying motor control. In the lower extremity, the most common pattern of spasticity is one of flexion. First, establish passive range of motion of each joint. Test by slow extension of the joint to avoid the velocity-sensitive response of the muscle spindle. When spasticity is significant and passive joint motion is limited, use a combined femoral and sciatic nerve block by using a local anesthetic. To evaluate passive joint motion in the entire lower extremity, perform combined femoral and sciatic nerve blocks by using a local anesthetic. Alternatively, examine the patient while he or she is under general anesthesia. This is usually done only when the patient is going to surgery for another reason.

Unmasking of primitive patterning reflexes further contributes to the motor impairment. Spasticity (hyperactive response to quick stretch), rigidity (resistance to slow movement), or movement dysontogeny may be present. The degree of spasticity within selected muscles can be graded clinically in response to a quick stretch as mild, moderate, or severe. There is surprising consistency between observers using this simple grading system. Another method of quantifying muscle tone, which is readily accessible and easily performed at the bedside, is to measure the amount of passive force generated by a passive quick stretch or during functional use of the limb. Intramuscular pressure can be measured by using a wick or slit catheter technique. The pressure generated within the muscle is proportional to the force of contraction (7,181).

Motor control can be graded in the extremity using a clinical scale (see Table 123.3) (112). The extremity may be hypotonic or flaccid and without any volitional movement (grade 1). A spastic extremity may be held rigidly without any volitional or reflexive movement (grade 2). Patterned or synergistic motor control is defined as a mass flexion or extension response involving the entire upper extremity. This mass patterned movement may be reflexive in response to a stimulus but without

**Table 123.9. Classification of EMG Activity**

| Class I | Normal phasic activity |
| Class II | Paretic or pathologic activity |
| Class III | Phasic prolongation activity |
| HPA | Mixed prolongation activity |
| HPC | Neuromuscular activity |
| Class IV | Facilitatory activity |
| Class V | Spastic response activity |
| Class VI | Absent activity |

volitional control (grade 3). It is also possible for a patient to initiate mass patterned movement volitionally (grade 4). Although patterned movement can often be volitionally initiated, it is a neurologically primitive form of motor control and of no functional use in the upper extremity. Selective motor control with pattern overlay is defined as the ability to move a single joint or digit with minimal movement in the adjacent joints when performing an activity slowly (grade 5). Rapid movements or physiologic stress make the mass pattern more pronounced. Selective motor control is defined as the ability to move a single joint or digit volitionally independently of the adjacent joints (grade 6). Observe the patient clinically in a variety of functional tasks.

Differentiating between the relative contributions of pain, increased muscle tone, and contracture to a limb deformity can be difficult. Anesthetic nerve blocks are extremely useful in assessing joint range of motion. The blocks can be easily performed without the use of special devices. By temporarily eliminating pain and muscle tone, patient cooperation is gained and the amount of myostatic contracture can be determined. By using local anesthetic blocks, the strength and motor control of the antagonistic muscle group can also be evaluated (Fig. 123.3).

Laboratory-Assisted Assessment of Gait and Motor Control

Clinical examination supported by laboratory studies is the mainstream of evaluation. The clinical questions of interest regarding a given muscle include the following: Does the patient have selective voluntary control over the given muscle? Is the muscle activated dysynergically (i.e., in antagonism to movement) when the patient attempts to move the relevant joint? Is the muscle resistant to passive stretch (i.e., spastic)? Does the given muscle have fixed shortening (i.e., contracture)? Given the degree of clinical effort, patient morbidity, and procedural costs involved in treating complicated movement dysfunction in patients with CVA and TBI, clinical examination alone may not be sufficient to answer these questions with a high degree of confidence.

Technology-driven laboratory assessments that include formal gait and motion analysis, dynamic EMG studies, and nerve blocks are helpful (7, 11, 24, 25, 26 and 27, 35, 42, 62, 69, 84, 105, 106, 110, 114, 115, 127, 128, 135, 145, 147, 148, 175, 176, 178, 179 and 180, 198, 203, 214, 220, 225, 231, 232, 233 and 234, 236, 239, 240, 241 and 242). Perform laboratory gait analysis preoperatively on all patients using a standard laboratory protocol. This consists of bidirectional, slow-motion video record. Ground reaction forces are recorded using a laser vector superimposed on the video. Ground reaction forces are recorded from a force plate mounted into the walkway. The force plate consists of a rigid platform suspended on strain gauge transducers fitted with strain gauges. Each supporting corner has three sensors set at right angles to one another, and the vertical load, horizontal shear force, and forces in the mediolateral direction are measured. Temporospatial parameters obtained include walking velocity, cadence, stride time, and measurements of symmetry of gait. Dynamic multichannel EMG is acquired with simultaneous measurements of joint motion (kinematics) in the lower extremity while walking. Joint motion is recorded using electrogoniometers. Surface electrodes are used for the superficial lower limb muscles and wire electrodes for the deep muscles such as tibialis posterior and long toe flexors.

Kinetic, kinematic, and dynamic EMG data assist the clinician in interpreting whether voluntary function (effort-related initiation, modulation, and termination of activity) is present in a given muscle and whether that muscle's behavior is also dysynergic (sometimes referred to as "out of phase" behavior). In addition, responses to different rates of passive stretch of the muscle before and after a local anesthetic nerve block can help the clinician distinguish between the dynamic, velocity-sensitive reflex resistance of spasticity versus passive muscle tissue stiffness and contracture. Somatosensory-evoked potentials (SEPs) and motor evoked potentials (MEPs) provide information on the integrity of the sensory and motor pathways and may be helpful in predicting recovery of motor function after stroke (93). Combined with clinical information, laboratory measurements of muscle function often provide the degree of detail and confidence necessary for making conservative and surgical treatment decisions.

By combining the findings in several previous studies of spastic patients from our institution the following classification of EMG activity was devised to standardize terminology and may be used for either the upper or lower extremity (Table 123.9) (105, 112, 117, 125, 126).

- Class I constitutes a normal phasic pattern with appropriate on and off EMG activity.
- Class II consists of EMG activity that, although phasic, begins prematurely and continues for a short period beyond the normal duration of activity for that muscle. This pattern is more commonly seen in the lower extremity.
- Class III consists of phasic activity with prolongation beyond the normal timing of the muscle. Class III activity can be further subdivided into three patterns, depending on the degree of prolongation.
- Class IIIA consists of phasic activity with a short period of low-intensity EMG activity extending into the next phase of the flexion-extension cycle secondary to mild spasticity.
- Class IIIB consists of phasic activity, with prolongation extending for at least half of the next phase of motion. This is indicative of a moderate amount of spasticity.
- Class IIIC represents a severely spastic muscle and consists of phasic activity with severe prolongation in which EMG activity is continued throughout the next phase of motion at a high intensity but the underlying phasic nature of the muscle activity is still distinguishable.
- Class IV consists of continuous EMG activity without phasic variations.
- Class V consists of EMG activity seen only in response to a quick stretch by the antagonist muscles. There is no volitional activation of the muscle. This pattern is common in the finger extensors.
- Class VI consists of absent EMG activity.

Clinical examples of common deformities follow.

Equinovarus Foot Deformity Dynamic EMG performed during walking illustrates the motor pattern responsible for the spastic equinovarus deformity (Fig. 123.10) (105, 109, 175, 176 and 177, 179, 180, 226, 227, 230, 231, 237, 241). The gastrocnemius and soleus muscles are spastic, causing the equinus posture of the foot. The tibialis anterior muscle is also spastic, resulting in the varus position of the forefoot. In stroke and brain injury, the tibialis posterior muscle is less commonly an offending force. When the tibialis posterior is overactive, excessive heel varus is seen (Fig. 123.11). The flexor digitorum longus (FDL), flexor hallucis longus, and intrinsic muscles of the foot are also spastic, resulting in curled toes.

Figure 123.11. Patient with an equinovarus deformity of the foot with pronounced inversion of the heel. This marked heel inversion usually indicates spasticity in the tibialis posterior muscle. Spasticity in the tibialis posterior muscle is seen in 10% of patients with UMN syndrome from stroke or brain injury.

Spastic Valgus Foot Spastic valgus deformities of the foot are less common in stroke and brain-injured patients but can easily be missed (Fig. 123.12). The valgus deformity may occur alone as a result of overactivity of the peroneus longus or brevis muscle (Fig. 123.13) (255). It may also occur during stance phase in combination with an equinovarus deformity that occurs during the swing phase of gait.
Malunions of both intertrochanteric and subtrochanteric hip fractures can be seen in TBI patients. They usually present with leg-length discrepancy, gait abnormalities, discrepancy without pelvic pain may be best managed with a shoe lift. Pain, and gait abnormalities (Pelvis and Hip). Fracture malunions are common in the TBI patient (Fracture Malunion). Patients who have had TBI or stroke present unique challenges to the surgical team. The patients may have behavioral deficits or cognitive limitations that would make them difficult to manage with regional anesthesia and sedation. Therefore, general anesthesia is preferred (70,208). These patients have often previously had tracheostomy performed; therefore, an anesthesia team familiar with airway difficulties caused by this procedure is important. Take great care when positioning these patients for long procedures because contractures of other portions of their bodies may increase the risk of pressure ulcer formation.

Orthopaedic Management of Common Lower Extremity Deformities

General Considerations

The patterns of limb spasticity seen following stroke and TBI are very similar. The same orthopaedic procedures can be used in both patient populations. The orthopaedic treatment interventions are described together. These procedures, however, are not applied equally to both patient groups. The degree of spasticity, the timing of neurologic recovery, and the pattern of spontaneous neurologic recovery are different between stroke and brain-injured patients. These differences account for the variation in the need for specific treatments between the two groups.

Patients who have had TBI or stroke present unique challenges to the surgical team. The patients may have behavioral deficits or cognitive limitations that would make them difficult to manage with regional anesthesia and sedation. Therefore, general anesthesia is preferred (70,208). These patients have often previously had tracheostomy performed; therefore, an anesthesia team familiar with airway difficulties caused by this procedure is important. Take great care when positioning these patients for long procedures because contractures of other portions of their bodies may increase the risk of pressure ulcer formation.

Fracture Malunion

Fracture malunions are common in the TBI patient (58,63,68,71,73,79,81,145,204,243,253) owing to a combination of factors. Trauma concurrent with the brain injury may cause complex fractures, which are predisposed to malunion. Injuries may be missed in the initial resuscitation, leading to malunion. The prognosis of the brain injury may be so poor that optimal internal fixation of fractures is not sought or obtained. Hemodynamic or pulmonary instability may cause optimal fracture fixation to be delayed. Poor patient compliance, agitation, and spasticity may alter the initial reduction. If these problems are not anticipated, malunion may result.

Pelvis and Hip

Pelvic malunion can occur following unreduced unstable pelvic fractures. Patients usually present with rotational deformities, leg-length discrepancy, pain, and gait abnormalities (23,63,145,253). The need for surgical correction must be individualized to each patient’s symptoms. For example, a small leg-length discrepancy without pelvic pain may be best managed with a shoe lift.

Malunions of both intertrochanteric and subtrochanteric hip fractures can be seen in TBI patients. They usually present with leg-length discrepancy, gait abnormalities,
and pain (see Fig. 123.1). These deformities can be managed with a corrective osteotomy after careful preoperative planning (186).

### Femur
There is no consensus on what represents a malunion of the shaft of the femur (12). An anterior bow is better tolerated than either a varus or a valgus alignment. Malalignment of fracture may lead to early degenerative arthritis at the knee joint secondary to increased pressure along the tibial plateau (130). Most deformities can be managed with a corrective osteotomy and intramedullary fixation.

### Tibia
Tibial malunions can lead to abnormal stresses across the ankle and knee. This malalignment can lead to degenerative changes at both the knee and ankle (130). Like the femur, corrective osteotomies can be performed to restore balance. External fixators can be employed for more complex deformities if intramedullary fixation is not possible.

### Ankle
Ankle malunions may also be seen in the TBI patient. The most common malunion of the ankle is shortening and malrotation of the fibula (221). A corrective osteotomy can be performed to restore length and re-establish alignment (246).

### Heterotopic Ossification

### Anterior Hip (Flexor)

Table 123.10. Functional Classes of the Brain-Injured Adult

### Pelvis and Hip

#### Anterior Hip (Flexor)
After TBI, HO typically occurs along the lines of tension caused by the spastic muscles. Anterior HO is seen to follow the quadriceps femoris muscle. Anterior HO usually extends from the anterior superior iliac spine (ASIS) and inner aspect of the pelvis to the proximal femur in the region of the lesser trochanter.

- When resecting anterior hip HO, perform a standard anterior approach to the hip, but also dissect the femoral triangle and its contents (see Chapter 2 and Chapter 3).
- Take care to identify all major divisions of the femoral artery, nerve, and vein. It is prudent to place vascular loops around all major vessels proximal to ensure easier control of bleeding should a major vessel be damaged during the procedure. A wide exposure and meticulous hemostasis are needed.
- Although all the neurovascular structures may be encased in HO, it is more common for the nerve to be entrapped (65). The femoral nerve is already divided into its many branches within the femoral triangle. The motor branches are small in diameter; carefully identify them.
- Because it is difficult to mobilize the neurovascular structures, remove the heterotopic bone in small segments. It is difficult to distinguish normal from abnormal bone. The morphology of the normal bone and the HO must be closely observed. Preoperative CT scans with three-dimensional reconstruction can be extremely helpful in understanding the morphology. Also use intraoperative radiographs or fluoroscopy to guide the resection (63,64 and 68,72,73,111,138,187,191).

#### Medial Hip (Adductor)
Heterotopic bone seen inferomedial to the hip joint follows the adductor muscles from the pubis and extends toward the medial aspect of the femur.

- Use a medial approach to the hip for resection. If there is a significant hip adduction contracture, release of the hip adductors may also be needed.
- Often, HO is seen both anterior and medial to the hip. In these cases, it is necessary to make two separate incisions and work between both.

#### Posterior Hip (Extensor)
Posterior HO lies immediately posterior to the femoral head and neck (see Fig. 123.2). Although posterior bone forms in conjunction with hip extensor spasticity, it is usually associated with a flexion contracture of the hip.

- Use a posterior approach to the hip for resection.
- Identify the sciatic nerve distally and dissect it proximally. It is common for the sciatic nerve to be encased within the mass of heterotopic bone. Significant scarring may also be seen around the sciatic nerve secondary to the intense inflammatory reaction that happens during the intermediate stages of bone formation. A neurolysis of the sciatic nerve may be needed.
- Once the sciatic nerve is identified, begin a more aggressive resection of the bone.
- If a significant hip flexion contracture persists after excision of the posterior HO, an anterior soft-tissue release may be necessary (63,64 and
Spasticity of the hip flexors can result in a crouched gait with compensatory knee flexion to prevent the iliopsoas from the lesser trochanter permits the iliopsoas to recess proximally, thereby diminishing its pull but retaining its function.

Thigh and Knee HO is less common in the thigh and the knee. When it does occur, it usually is seen medially and may appear as a Pellegrini-Stieda lesion. Even when the medial HO does not bridge the joint, it commonly causes a knee flexion contracture by placing tension on the surrounding tissues. When there has been knee extensor spasticity, the HO can be found along the distal shaft of the femur beneath the quadriceps muscle. It often wraps around both the medial and lateral sides of the femur and greatly restricts knee motion (63, 64 and 65). Posterior HO is uncommon after head injury but can occur in conjunction with hamstring spasticity (37, 69, 87, 88, 153, 192, 212).

Perform surgical resection of the HO if knee motion is limited. The choice of the surgical approach depends on the location of the HO.

When a medial approach is needed, split the collateral ligament longitudinally and strip it from its insertion. Use a hinged brace postoperatively until the medial collateral ligament has reattached and the knee is stable.

When there is extensive HO beneath the quadriceps, it is often necessary to make both medial and lateral incisions and remove the ectopic bone from beneath the muscle. Preserve the integrity of the quadriceps to allow for immediate mobilization after surgery.

If a posterior approach is chosen, first identify the neurovascular structures proximally and dissect down to the HO. Continuous passive motion devices are helpful postoperatively.

**SPASTIC HIP DEFORMITIES**

**Adduction Deformity**

**Obturator Neurectomy** Scissoring of the legs in an ambulatory patient gives the patient a narrow base of support while standing and results in poor balance. A preoperative obturator nerve block eliminates the adductor spasticity and allows assessment of the adduction contracture (127). Alternatively, the patient can be examined at the time of surgery while under anesthesia to determine if a fixed myostatic contracture is present. When no fixed adduction contracture is present, transection of the anterior branches of the obturator nerve will denervate the adductors and allow the patient a broader base of support (16, 25, 26, 28, 78, 89, 108, 123, 127, 138, 151, 155, 156, 159, 179, 184, 203, 225, 227).

Commonly, a small contracture is found and the adductor longus muscle is released at the time of the obturator neurectomy.

- Make a longitudinal incision directly over the adductor longus muscle.
- Release and retract the adductor longus muscle.
- Transect the anterior branch of the obturator nerve over the muscle belly of the adductor brevis.

**Hip Adductor Tenotomy** A hip adduction contracture that interferes with nursing care and hygiene in a nonambulatory patient or excessive limb scissoring during attempted transfers and ambulation in a patient with active function are indications for surgical release (16, 25, 26, 28, 78, 89, 108, 123, 127, 138, 151, 156, 159, 179, 184, 203, 225, 227). In a severely spastic patient, a flexion contracture of the hip and knee commonly occurs in conjunction with an adduction contracture. As for any contracture, obtain preoperative radiographs before performing soft-tissue releases to rule out the presence of HO or an underlying bony deformity that would prevent correction.

- With the patient in the supine position, make a longitudinal incision over the adductor longus muscle.
- Place the incision distal to the groin crease to position the incision in a more hygienic location.
- Use a longitudinal incision to decrease tension on the wound edges as the leg is brought into a corrected position after surgery.
- Dissect the adductor longus muscle free and transect it using electrocautery.
- Identify and transect the anterior branches of the obturator nerve.
- Release the adductor brevis and gracilis close to their pelvic origin (Fig. 123.15).

**Figure 123.15.** Release of the spastic hip adductor muscles. The adductor longus, adductor brevis, and gracilis muscles are released through a medial groin incision. The adductor magnus is rarely released.

- Close the wound over a drain.

Daily wound care is essential to prevent infection in this potentially contaminated area. Keep the hips in abduction for 4 weeks using casts or an abduction pillow splint to prevent recurrence of the deformity during wound healing.

**Flexion Deformity**

**Functional Release—Pectineus Release with Iliopsoas Recession** Spasticity of the hip flexors can result in a crouched gait with compensatory knee flexion to maintain balance. This is a very costly deformity because it requires constant use of the quadriceps, hip extensor, and calf muscles to maintain upright posture. The energy requirement for the continuous firing of these muscles is extremely high. Few patients are able to remain ambulatory with this deformity.

The hip flexor muscles are needed to advance the limb during gait. Avoid complete release of the hip flexors in any patient with the potential to ambulate. Because the iliopsoas has capsular insertions, release of the iliopsoas tendon from the lesser trochanter of the femur does not provide a complete release. Release of the tendon from the lesser trochanter permits the iliopsoas to recess proximally, thereby diminishing its pull but retaining its function.

- Use a medial approach to the hip. Make a longitudinal incision overlying the adductor longus tendon beginning 3 cm distal to the pubic tubercle.
- Bluntly develop a plane between the adductor longus and gracilis muscles.
- Continue the dissection between the adductor brevis and adductor longus muscles.
- Identify and protect the anterior division of the obturator nerve.
- If an adduction deformity is also present, perform division of the adductor longus muscle. This facilitates exposure of the deeper muscles.
- Identify the pectineus muscle as it lies deep to the femoral vessels and medial to the adductor longus.
- Divide the pectineus muscle using electrocautery. The lesser trochanter of the femur can be palpated in the depth of the wound.
- Visualize the tendon of the iliopsoas by placing narrow reverse retractors above and below the lesser trochanter.
- Divide the iliopsoas tendon from the trochanter and allow it to retract proximally (Fig. 123.16).
A hip flexion contracture or severe spasticity in a nonambulatory patient that causes poor release of the proximal origin of the hamstring muscles is indicated (123.18). Extension Deformity ability to sit in a chair may be severely compromised.

With a bar to hold the legs in neutral rotation and slight abduction. If the hip is allowed to position in flexion, abduction, and external rotation while healing occurs, the very important to maintain the leg in a neutral position for at least 3 months while soft-tissue healing occurs. This can be done with bilateral short-leg casts connected not advisable merely to resect the femoral head because this approach will not treat the spasticity and a more severe leg deformity can occur. After this surgery, it is most common with anoxic encephalopathy. The hip joint has advanced osteoarthrosis and is painful. The hip pain increases the spasticity, which, in turn, causes more

As with release of other contracted joints, approximately 50% of the deformity will be corrected at the time of surgery. Daily wound care will help prevent infection in this area where bacterial contamination is likely. Place the patient in a prone position three times a day for increasing periods and institute gentle stretching exercises to assist in correcting any residual hip flexion deformity. When a release of a knee flexion contracture has been performed simultaneously, the weight of the long-leg cast will also provide a correcting force. Allow sitting in a wheelchair for short periods.

With the patient in the supine position, make an anterior incision beginning 2.5 cm distal to the anterior superior iliac spine. Carry it distally following the sartorius muscle for a short distance. The incision should not extend over the iliac crest because the patient will be expected to lie in the prone position postoperatively to gain further correction of the deformity.

Identify the lateral femoral cutaneous nerve as it passes distal to the anterior superior iliac spine and protect it. Detach the sartorius muscle from its origin on the anterior superior iliac spine. Release the rectus femoris muscle from its origin on the anterior inferior spine of the pelvis. Gently retract the femoral nerve and vessels medially to expose the iliopsoas muscle on the anterior aspect of the hip.

Carefully divide the iliopsoas and pectineus muscles over the pelvic brim by using electrocautery to diminish postoperative bleeding. Because the iliopsoas has capsular insertions, release of the iliopsoas tendon from the lesser trochanter of the femur does not provide a complete release. The tensor fascia lata and the anterior portion of the gluteus medius and glutaeal aponeurosis may be released from the iliac crest if necessary. The hip joint capsule is not released (Fig. 123.17). In a severely contracted patient, take care to identify all structures before release because the anatomy is frequently distorted by the longstanding deformity. A large dead space is left after releasing the hip flexor muscles, and a drain should be used. Carefully close the wound and apply a compressive dressing, which is helpful in preventing postoperative infection.

As with release of other contracted joints, approximately 50% of the deformity will be corrected at the time of surgery. Daily wound care will help prevent infection in this area where bacterial contamination is likely. Place the patient in a prone position three times a day for increasing periods and institute gentle stretching exercises to assist in correcting any residual hip flexion deformity. When a release of a knee flexion contracture has been performed simultaneously, the weight of the long-leg cast will also provide a correcting force. Allow sitting in a wheelchair for short periods.

On occasion, a patient is seen with chronic hip subluxation or dislocation from severe and very longstanding hip flexion and adduction spasticity. Both problems are most common with anoxic encephalopathy. The hip joint has advanced osteoarthrosis and is painful. The hip pain increases the spasticity, which, in turn, causes more pain and so on in a circular fashion. In these cases, it is usually necessary to resect the femoral head at the same time as performing a complete muscle release. It is not advisable merely to resect the femoral head because this approach will not treat the spasticity and a more severe leg deformity can occur. After this surgery, it is very important to maintain the leg in a neutral position for at least 3 months while soft-tissue healing occurs. This can be done with bilateral short-leg casts connected with a bar to hold the legs in neutral rotation and slight abduction. If the hip is allowed to position in flexion, abduction, and external rotation while healing occurs, the ability to sit in a chair may be severely compromised.

Extension Deformity

Proximal Hamstring Release Following a severe brain stem injury, spasticity of the extensor muscles of the leg may result in a hip extension contracture (Fig. 123.18). Although this problem is uncommon, an extension contracture will interfere with a person's ability to sit. When good sitting posture cannot be obtained, a release of the proximal origin of the hamstring muscles is indicated (56,123,200,201).
Place the patient in the prone position for surgery.
- Make a longitudinal incision over the posterior thigh beginning at the gluteal fold.
- Identify and protect the posterior femoral cutaneous nerve.
- Lift the distal edge of the gluteus maximus proximally to expose the underlying hamstring muscles.
- Then detach the biceps femoris, semimembranosus, and semitendinosus muscles from their origins on the ischial tuberosity and allow them to retract distally.

Postoperatively, start the patient on gentle passive range-of-motion exercises to regain hip flexion.

**SPASTIC KNEE DEFORMITIES**

**Flexion Deformity**

**Distal Hamstring Lengthening** A knee flexion deformity is caused by overactivity of the hamstring muscles (6,88,105,120,241). When the knee flexion deformity is less than 60° and the patient has documented volitional activity in the hamstring muscles, perform a lengthening procedure. This approach will correct the flexion deformity while preserving the function of the hamstrings.

- With the patient in the supine position, make a longitudinal incision of approximately 8 cm on the lateral aspect of the distal thigh just proximal to the knee joint (see Fig. 123.7).
- Isolate and protect the peroneal nerve and divide the biceps femoris tendon obliquely as it overlies the muscle belly. This allows the tendon to slide distally while still maintaining continuity of the muscle.
- Also divide the portion of the iliotibial band that is posterior to the axis of knee flexion transversely.
- Then make a longitudinal incision on the medial aspect of the distal thigh.
- Isolate the tendons of the gracilis and semimembranosus and fractionally lengthen them at the myotendinous junction by making an oblique cut in the tendon as it overlies the muscle belly (see Fig. 123.7). The semitendinosus tendon has a very short myotendinous junction, which does not permit fractional lengthening. Simply transect this tendon.

After surgery, immobilize the extremity in a long-leg cast. Approximately 50% correction of the knee flexion deformity can be expected at the time of surgery. Further correction is limited due to tethering of the neurovascular structures. Cast the extremity in the position of knee extension it assumes while being supported under the heel, without attempting forced extension. Forced knee extension can result in limb ischemia. Change the long-leg cast weekly until full knee extension has been obtained. Use splints at night for an additional 4 weeks to maintain correction.

**Distal Hamstring Release** In a nonambulatory patient with a marked increase in hamstring muscle tone, knee flexion contractures result (103,105,108,120,122,123,127,169,174,184,203,230). Spasticity is frequently present. When severe spasticity of the hamstring muscles or a knee flexion contracture of greater than 60° is present, attempts to correct the knee position with casting or bracing may result in posterior subluxation of the tibia. Distal release of the hamstring tendons does not prevent a patient from becoming ambulatory. If the hip flexion contracture or spasticity is not corrected at the same time as the hamstring release, a recurrent knee flexion contracture is likely to develop that is very resistant to surgical correction.

- With the patient in the supine position, make a longitudinal incision of approximately 8 cm on the lateral aspect of the distal thigh just proximal to the knee joint (Figs. 123.19).
- Isolate the peroneal nerve and divide the biceps femoris tendon obliquely as it overlies the muscle belly. This allows the tendon to slide distally while still maintaining continuity of the muscle.
- Then make a longitudinal incision on the medial aspect of the distal thigh.
- Isolate and protect the peroneal nerve and divide the biceps femoris tendon obliquely as it overlies the muscle belly. This allows the tendon to slide distally while still maintaining continuity of the muscle.
- Also divide the portion of the iliotibial band that is posterior to the axis of knee flexion transversely.
- Isolate the tendons of the gracilis and semimembranosus and fractionally lengthen them at the myotendinous junction by making an oblique cut in the tendon as it overlies the muscle belly (see Fig. 123.7). The semitendinosus tendon has a very short myotendinous junction, which does not permit fractional lengthening. Simply transect this tendon.

After surgery, immobilize the extremity in a long-leg cast. Approximately 50% correction of the knee flexion deformity can be expected at the time of surgery. Further correction is limited due to tethering of the neurovascular structures. Cast the extremity in the position of knee extension it assumes while being supported under the heel, without attempting forced extension. Forced knee extension can result in limb ischemia. Postoperatively, change the long-leg cast weekly until full knee extension has been obtained. Have the patient use splints or a knee immobilizer at night for an additional 4 weeks to maintain correction.
Extension Deformity

Rectus Femoris to Gracilis Transfer for Dynamic Stiff-knee Gait Patients with a stiff-knee gait are unable to flex the knee during the swing phase of gait. The deformity is a dynamic one, meaning that it only occurs during walking. There is no restriction of passive knee motion, and the patient does not have difficulty sitting. Usually, the knee is maintained in extension throughout the gait cycle. Toe drag, which is likely in the early swing phase, may cause the patient to trip; thus, balance and stability are also affected. The limb appears to be longer functionally. Circumduction of the involved limb, hiking of the pelvis, or contralateral limb vaulting may occur as compensatory maneuvers.

Fig. 123.21. A stiff-knee gait is caused by inappropriate activity in the quadriceps muscles, which inhibits knee flexion. The patient must hike the hemipelvis and circumduct the leg to clear the foot during swing. (From Keenan MAE, Kozin SH, Berlet AC. Manual of Orthopaedic Surgery for Spasticity. New York: Raven Press, 1993, with permission.)

Preoperatively, conduct a gait study with dynamic EMG to document the activity of the individual muscles of the quadriceps (see Fig. 123.14). Dysynergic activity is commonly seen in the rectus femoris muscle from preswing through terminal swing throughout the gait cycle. Abnormal activity is also common in the rectus intermedius muscle. If knee flexion is improved with a block of the rectus femoris or vastus intermedius muscle, the rationale for surgical intervention is strengthened. Any equinus deformity of the foot should be corrected before evaluation of a stiff-knee gait because equinus causes a knee extension force during stance. The amount of knee flexion during swing is directly related to the speed of walking, so the patient should be able to ambulate with a reasonable velocity in order to benefit from surgery. Hip flexion strength is also needed for a good result because it is the forward momentum of the leg that normally provides the inertial force to flex the knee. In the past, a selective release of the rectus femoris muscle or rectus and vastus intermedius muscles was performed to remove their inhibition of knee flexion. On average, a 15° improvement in peak knee flexion was seen after surgery. Transfer of the rectus femoris to a hamstring tendon not only removes it as a deforming muscle force, it also converts the rectus into a corrective (flexion) force. This procedure provides improved knee flexion over selective release.

- Make a longitudinal incision on the anterior thigh from 10 cm above the patella to the middle aspect of the patella.
- Dissect the rectus femoris muscle free from the other vasti muscles both proximally and distally.
- Carry the dissection distally to the patella and also remove a strip of perισteum from the patella to gain additional length. If significant spasticity was seen in the vasti muscle on the dynamic EMG study, these muscles are fractionally lengthened by transecting their tendons as they overly the muscle belly.
- Make a second incision over the medial hamstring structures proximal to the knee.
- Identify the gracilis tendon.
- Then make a subcutaneous tunnel between the two incisions and through the intermuscular septum.
- Pass the distal end of the rectus femoris tendon through the tunnel to the medial wound, with the knee flexed 90° and the femur externally rotated.
- Sew the rectus femoris tendon to the gracilis tendon (Fig. 123.22) by means of a Pulvertaft weave. We prefer to use the gracilis as our transfer site as opposed to the sartorius because of the strong tendon repair possible. The gracilis also provides a more posterior attachment of the transfer, which, in turn, increases the flexor moment created.

Fig. 123.22. The rectus femoris is transferred to the gracilis tendon to improve knee flexion during the swing phase of gait.

Transfer the rectus muscle under considerable tension.
- Then gently extend the knee to be certain that full knee extension can still be obtained. The location of the transfer has not been shown to affect range of motion of the knee.

Postoperatively, place the patient in a knee immobilizer splint for 1 week to prevent a knee flexion deformity from occurring secondary to the tension and to prevent discomfort of the transfer. The patient can begin gait training in the immobilizer on the first postoperative day. Because of the good fixation into the gracilis tendon, start knee range of motion and ambulation without the splint 1 week later. Stress a marching gait pattern during therapy to facilitate knee flexion during swing.

Quadriceps Lengthening After a brain stem injury, extensor spasticity can cause a knee extension contracture. This is usually seen in combination with a hip extension contracture. Both deformities result in problems with sitting. The knee extension deformity can be corrected by lengthening the quadriceps. Quadriceps weakness is not a problem in these patients because they are not ambulatory. In the past, a V-Y lengthening of the quadriceps tendon was routinely performed. We have more recently been performing a fractional lengthening of the individual muscles of the quadriceps. This procedure is more easily performed and has a lower morbidity rate than the V-Y lengthening. It also does not cause a patella baja deformity. Even severe hyperextension knee deformities can be corrected with this procedure.

- Make a longitudinal incision over the anterior thigh at the junction of the middle and distal third of the quadriceps muscle.
- Dissect the rectus femoris tendon free from the vasti at this level. This is easily done.
- There is a long overlap of the rectus muscle and tendon on the undersurface of the muscle belly. Sharply transect the tendon over the muscle belly, leaving the underlying muscle intact. The rectus tendon to be the most contracted muscle and two cuts are often made in the tendon.
- Beneath the rectus femoris muscle, locate the myotendinous junctions of the vastus intermedius, medialis, and lateralis muscles. Individually transect each tendon over the muscle belly.
- Then gently and slowly flex the knee to at least 120°. The quadriceps muscles can be seen to lengthen as the knee is flexed.
- Close the wound in a routine manner.

Postoperatively, have the patient perform passive knee flexion several times daily to maintain knee flexion. Permit the patient to sit as much as tolerated. Immobilization is not needed.

SPASTIC FOOT AND ANKLE DEFORMITIES

Equinus

SPASTIC FOOT AND ANKLE DEFORMITIES
Achilles Tendon Lengthening  Equinus is the most common spastic deformity that causes gait difficulty (Fig. 123.23) (4, 101, 105, 109, 110, 140, 143, 174, 175, 176, 177 and 178, 180, 182, 195, 231, 241). Equinus results from the overactivity or premature activity of the gastrocnemius and soleus muscles. Surgical lengthening of the Achilles tendon is indicated when the patient’s foot and ankle position is not adequately controlled by an orthosis or when attempting to make the patient brace free. Adequate lengthening of the Achilles tendon can be performed using the Hoke triple hemisection technique percutaneously (Fig. 123.24).

Figure 123.23. Patient with a spastic equinovarus deformity of the foot.

Equinus and toe curling usually accompany the varus deformity, so a lengthening of the Achilles tendon should be performed first and the toe flexor tendons divided.

- With the foot held in maximum dorsiflexion, make three percutaneous hemitransections of the Achilles tendon using a #11 knife blade.
- If a varus deformity of the foot is present, make the proximal and distal cuts in the medial half of the tendon, and place the center cut laterally.
- Then push the foot into dorsiflexion, allowing the tendon to lengthen.

Postoperative management requires 6 weeks of rigid immobilization. We begin by using a short-leg walking cast for 2 weeks. We then use a cam walker boot for the next 4 weeks. At this time, we allow the patient to remove the boot once daily for bathing and skin care, provided that the patient does not stand or walk without the boot. After this, the patient uses an AFO for an additional 6 weeks.

Varus  Split Anterior Tibial Tendon Transfer  Varus deformities most commonly occur as the result of increased and innappropriate activity of the tibialis anterior muscle (see Fig. 123.10). When the tibialis anterior has been documented by dynamic EMG to be a cause of varus, the deformity can be corrected by a split anterior tibial tendon transfer (SPLATT). The SPLATT maintains the half of the tendon on the medial aspect of the foot and transfers the other half of the tibialis anterior tendon to the lateral side of the foot (Fig. 123.25) (4, 101, 105, 109, 127, 184, 203, 226, 230, 241).

Figure 123.25. The split anterior tibialis tendon transfer for correction of varus caused by overactivity of the tibialis anterior muscle.
and skin care. The foot must be maintained in a neutral position while the boot is off and no weight bearing is allowed. Six weeks after surgery, use a nonarticulated, moderately rigid AFO for an additional 6 weeks. The patient must sleep wearing the AFO during this time to protect the foot from inadvertent stretch. At 3 months after surgery, the brace can be removed for sleeping and gait training. Discontinue the AFO if and when the patient has established sufficient strength in the calf muscles to permit safe walking.

**Tibialis Anterior Lengthening** Occasionally, a mild varus deformity is seen during walking that is due to a moderate increase in tibialis anterior activity. In this situation, a myotenous lengthening is sufficient to control the varus deformity.

- Make an incision over the tibialis anterior muscle approximately 10 cm proximal to the ankle joint.
- Open the fascial sheath of the tibialis anterior and transect the tendon over the muscle belly of the tibialis anterior, thereby allowing the muscle to lengthen fractionally.

If this is the only procedure performed, no immobilization is needed after surgery. Allow full weight-bearing ambulation immediately.

**Tibialis Posterior Lengthening** In approximately 10% of stroke and brain-injured patients the tibialis posterior muscle is also spastic and can contribute to the varus deformity (105,109,231). Clinically, this is evidenced by the increased heel varus in addition to the forefoot varus caused by the tibialis anterior muscle (see Fig. 123.11).

When spasticity of the tibialis posterior muscle is present, perform a myotenous lengthening by transecting the tendon as it overlies the muscle belly, posterior and slightly proximal to the medial malleolus. Complete release of the tibialis posterior tendon is not recommended because a secondary planovalgus deformity may occur.

**Extensor Hallucis Longus Lengthening** With the equinovarus deformity, the patient may also have a hitchhiker’s great toe secondary to spasticity of the EHL tendon (59,60,147,148). The EHL also contributes to the varus deformity of the forefoot. Many patients with this condition complain of shoe wear problems from pressure of the halluc against the shoe.

- Make a 3 cm incision over the anterior leg, beginning 10 cm proximal to the ankle joint. Identify the EHL muscle and fractionally lengthen it by transecting the tendon as it overlies the muscle belly.

If no other surgical procedures are needed, then no immobilization is needed after surgery. Most commonly, the EHL is lengthened in combination with a SPLATT procedure. In this situation, follow the postoperative protocol of the SPLATT.

**Valgus**

**Peroneal Lengthening** Spastic valgus foot deformities are less common in the stroke and brain injury population. The deformity can result from overactivity of the peroneus longus, peroneus brevis, or both (252). Use dynamic EMG to determine which muscles are causing the deformity.

If the deformity is not severe, consider a myotenous lengthening.

- Make an incision over the lateral leg, approximately 10 cm above the ankle joint.
- Open the fascia of the lateral compartment and fractionally lengthen the offending peroneal muscles.

If no other procedures are performed simultaneously, no immobilization is needed after surgery. Allow unrestricted ambulation.

**Peroneus Longus Transfer** A spastic valgus deformity may result from overactivity of the peroneus longus muscle. This problem can occur as an isolated deformity but more commonly occurs in combination with spastic equinovarus (123,252). In the “spastic combination foot” deformity, equinovarus is observed during swing phase from premature and prolonged firing of the tibialis anterior and gastro-soleus muscles. The planovalgus deformity occurs during stance from the inappropriate activity of the peroneus longus muscle. The pronation deformity may be accentuated by a premorbid tendency to flat foot or by the presence of an equinus contracture.

When a severe spastic valgus occurs, the peroneus longus tendon is transferred through the interosseous membrane to the tarsal navicular bone to support the longitudinal arch of the foot during stance.

- Make a small incision on the lateral border of the foot just proximal to the base of the fifth metatarsal (Fig. 123.26).
- Identify the peroneus longus and brevis tendons.
- Divide the peroneus longus tendon to obtain maximal length.
- Make a second incision over the lateral leg approximately 10 cm above the ankle.
- Identify the peroneus longus muscle and pull the distal end of the tendon proximally into this wound.
- Make a third incision over the anterior leg 10 cm proximal to the ankle.
- Carry the dissection down to expose the interosseous membrane.
- Make a window in the interosseous membrane and pass the peroneus longus tendon through to the anterior leg wound.
- Make a final incision over the navicular bone on the medial side of the foot.
- Use a drill to create a tunnel through the navicular bone.
- Then pass the peroneus longus tendon subcutaneously to the medial foot using a long forceps.
- Pass the end of the tendon through the tunnel in the navicular and secure it back to itself using nonabsorbable sutures. Secure the tendon to hold the foot in a neutral alignment.
- Place the patient in a short-leg walking cast at surgery, holding the foot in a neutral alignment.

When a combined deformity is present, perform a split anterior tibial tendon transfer along with an Achilles tendon lengthening and toe flexor release to correct the swing phase abnormalities.

Start gait training on the first postoperative day, allowing the patient to bear full weight on the foot as tolerated. Keep the cast on the foot for 2 weeks, and then remove the cast and sutures. Then place the patient in a cam walker boot for the next 4 weeks. With reliable patients, we allow the cam boot to be removed once daily for washing and skin care. The foot must be maintained in a neutral position while the boot is off, and no weight bearing is allowed. Six weeks after surgery, use a nonarticulated, moderately rigid AFO for an additional 6 weeks. The patient must sleep wearing the AFO during this time to protect the foot from an inadvertent stretch. At 3 months after surgery, the brace can be removed for sleeping and gait training. Discontinue the AFO if and when the patient has established sufficient strength in the calf muscles to permit safe walking.
Cavus

Steindler Stripping A cavus deformity is defined as an elevated arch that does not flatten with weight bearing. The deformity is probably a result of muscle imbalance of both the intrinsic and extrinsic muscles of the foot (111). If the foot is supple, a soft-tissue procedure can be performed; however, if the foot is rigid, a bony fusion must be performed. Steindler stripping is the release of the plantar structures.

- Expose the plantar fascia through a medial foot incision. Take care to identify and preserve the medial calcaneal nerve branches to the heel pad.
- Release the origin of the fascia under direct vision.
- Identify the origin of the abductor hallucis and elevate it from the tuberosity of the os calcis.
- Also release the origin of the flexor brevis and intrinsic muscles of the foot.
- Then passively correct the foot and place it into a short-leg cast.

Keep the short-leg cast for 2 weeks. Start weight bearing on the first postoperative day. Because this procedure is usually done in combination with the SPLATT operation, the SPLATT protocol is generally followed.

Triple Arthrodesis For severe rigid bony deformities, a triple arthrodesis is performed to correct the foot (146). Most commonly, this procedure is performed in combination with a plantar release (Steindler stripping) and the SPLATT procedure.

- Make an incision over the lateral foot from the tip of the fibula to base of the fourth metatarsal.
- Elevate the extensor brevis and fat pad to expose the calcaneocuboid joint and the sinus tarsi. Remove the superior process of the distal calcaneus by using an oscillating saw to facilitate exposure. Save the bone to use as graft later.
- Insert a lamina spreader between the talus and calcaneus to expose the joint surfaces further.
- Denude the posterior and middle facets of the subtalar joint of cartilage.
- Also expose the calcaneal cuboid joint and remove the cartilage.
- Expose the lateral talonavicular joint and prepare it through the same incision.
- Make a small medial incision over the talonavicular joint and remove the remaining cartilage. At this time, fix the three joints with three large-diameter cannulated screws and confirm their placement by fluoroscopic guidance.

Postoperatively, place the patient in a short-leg walking cast for 6 weeks. With the rigid fixation provided by the screw fixation, weight bearing is permissible. If sufficient bony union is seen at 6 weeks after surgery, allow the patient to use a rigid, nonarticulated AFO for ambulation. Protect the fusion until full bony healing is seen.

Clawfoot

Toe Flexor Release Toe clawing or curling is a common accompaniment of overactivity of the gastrocnemius muscles. Toe curling is caused by overactivity of the flexor hallucis longus and flexor digitorum muscle as well as the short toe flexor and occasionally the intrinsic muscles of the foot (110).

- Make a longitudinal incision on the plantar surface of each toe at the metatarsal phalangeal joint level. Identify the flexor tendons and release them under direct vision (Fig. 123.27). Also see Chapter 113.

Figure 123.27. Release of the long and short toe flexor tendons at the base of each toe.

This procedure is commonly performed in combination with an Achilles tendon lengthening because bringing the foot into a plantigrade position will worsen the toe curling. When an Achilles tendon lengthening has been performed, immobilize the foot for 3 months as described for that procedure.

Calf Paresis

Transfer of the Flexor Digitorum Longus to Os Calcis Muscle paresis (weakness) is an integral part of UMN syndrome. Lengthening the Achilles tendon to correct an equinus deformity weakens the gastrocnemius-soleus muscle group, which was already weak as a consequence of the underlying UMN syndrome. This calf paresis generally results in the need for an AFO during ambulation. Thus, transfer of the FDL muscle can be done to augment calf strength (Fig. 123.28). With this transfer, more patients eventually achieve brace-free ambulation (124). In prior studies of treatment of a spastic equinovarus foot deformity, 30% of patients were able to walk safely without an AFO (108). When the strength of the gastrosoleus is augmented by transfer of the FDL to the os calcis, 70% of patients achieve brace-free ambulation (124).

Figure 123.28. Transfer of the flexor digitorum longus tendon to the os calcis to augment the strength of the gastrocnemius and soleus muscles.

- Make a 4 cm incision on the medial border of the foot dorsal and parallel to the abductor hallucis muscle. Reflect the abductor hallucis plantarward from the base of the first metatarsal and isolate the flexor hallucis longus and FDL through the deep fascia at the master knot of Henry. At this level, the FDL has not yet split into four tendons and the FHL is easily dissected free.
- If the flexor brevis tendons are to be released simultaneously to correct toe curling, release them before transecting the FDL tendon.
- Dissect the FHL and FDL at the knot of Henry.
- Then make a 5 cm incision at the medial supramalleolar region, where the muscle belly of the FDL is isolated with its tendon and delivered through the medial supramalleolar incision.
- Make a 1 cm incision over the medial posterior superior os calcis.
- Use a 10-inch drill to create a tunnel through the posterior superior calcaneus, exiting on the lateral side.

![Image 72x1018 to 100x1047]

By using a systematic approach and dividing problems into both functional and anatomic categories, it is easier to sort through the numerous musculoskeletal issues. Transfer of a muscle-tendon unit redirects a muscle force. It is not necessary for the muscle to have normal control. It is critical that the transferred muscle has a predictable, nonvariable action to achieve the desired result. Varying muscle activity, such as in athetosis, is a contraindication to tendon transfer. Do not guess at which muscles are causing a deformity. Clinical assessment alone is unreliable to determine the causes of a spastic limb deformity. There are at least twenty different combinations of muscle activity that can cause an equinovarus foot posture. Dynamic poly-EMG studies or diagnostic nerve blocks are needed to assess the problem fully. The outcome of surgical correction depends on the accuracy of the preoperative assessment.

**AUTHOR’S PERSPECTIVE**

Patients with complex UMN disorders can initially be overwhelming to an orthopaedic surgeon. However, the care of these patients follows standard, well-known orthopaedic principles. Considering the specific limb problems individually and then constructing a prioritization list is the most effective method of dealing with patients who have multiple problems. As a starting point, it is helpful to consider problems in functional categories and next to consider whether or how correction of a specific limb deformity is likely to improve the function. Examples of functional categories include dressing, eating, transfers, and walking.

Limb function can be either active or passive. Passive function refers to problems of passive manipulation of limbs to achieve functional ends. Problems of passive function typically relate to activities such as dressing, bathing, sitting, or transfers. Problems of active function refer to a patient’s direct use of a limb to carry out the functional activity. It is a useful construct to categorize problems of function as being either passive or active in nature.

Walking is a commonly desired goal for patients and their caregivers. A patient with a severe equinovarus foot deformity often is unable to walk. If the patient has some active hip flexion to provide limb advancement and good sitting balance, then correction of the foot deformity is likely to make the patient ambulatory. It may also be necessary to correct a hand contracture for the patient to use a cane or walker to achieve this goal. If the patient lacks active hip flexion and has poor trunk balance, then correction of the foot deformity will not allow walking. Correction of the foot may still be useful to allow shoe wear or to improve sitting balance with the foot resting on the lever support of a wheelchair. By using a systematic approach and dividing problems into both functional and anatomic categories, it is easier to sort through the numerous musculoskeletal issues faced by persons with neurologic disorders. A major improvement in function and quality of life is achieved for many, giving both the surgeon and the patient a feeling of satisfaction and accomplishment.

CHAPTER 124

HETEROTOPIC OSSIFICATION AND CHARCOT NEUROARTHROPATHY

Gary Shapiro and Mathias Bostrom

G. Shapiro and M. Bostrom: Hospital for Special Surgery, New York, NY, 10021.

Heterotopic Ossification

DEFINITION

Formation of mature lamellar bone in nonosseous tissue is termed heterotopic ossification (HO) or heterotopic bone. Histologically, it differs from soft-tissue calcification in terms of its osteoblastic activity. Myositis ossificans is histologically identical to HO but, by definition, forms in inflammatory muscle. Periarticular calcification does not manifest the radiologic features of organized bone and is usually limited to distinct structures, such as the collateral ligaments. HO is metabolically active and histologically similar to native bone, with increased numbers of osteoblasts and osteoclasts.

ETIOLOGY

The pathogenesis of HO is not fully understood, although it is clearly associated with certain clinical situations. HO can result in severe limitation of motion and ankylosis. Chalmers et al. (19) proposed three conditions necessary for HO formation: an osteogenic precursor cell, an inducing agent, and an environment conducive to osteogenesis. Mesenchymal cells, which have the ability to differentiate to osteogenic stem cells, are found in the soft tissues surrounding joints. Osteoinductive substances are probably released as a result of the insult, and they may cause a proliferation of mesenchymal cells. Growth factors, such as bone morphogenetic proteins (BMPs), are potential inducers of undifferentiated mesenchymal cells to proliferate and differentiate into cartilage and bone and may play a role in the formation of HO (125,126).

LABORATORY ASSESSMENT

The preoperative identification of patients who are at risk has been investigated with bone scans and with laboratory tests, such as erythrocyte sedimentation rates (ESRs) and alkaline phosphatase levels. The results of these tests do not always correlate well with the development of the condition Theoretically, an immediate postoperative change in the serum level of substances related to osteoblast activity, such as osteocalcin, circulating growth factors, or the bone isoenzyme of alkaline phosphatase, might aid in the selection of high-risk patients needing prophylaxis. Most investigators have observed an increase in the serum alkaline phosphatase up to 3.5 times normal, beginning in the first month of HO and peaking at about 3 months (84). However, by the time these levels are noted to be elevated, the process is well established and prophylaxis is unlikely to be useful.

There has not been any conclusive evidence in the literature with regard to which test is the most accurate predictor of HO formation and maturation. Despite this, most surgeons usually allow a triple-phase bone scan and alkaline phosphatase to return to baseline before resecting heterotopic bone. Computerized tomography is often useful for operative planning.

CLASSIFICATION

The most common classification scheme used clinically is the Brooker classification, which is based on the extent of HO seen on the AP radiograph of the hip (Table 124.1). Wright et al. (131) tested the reliability and validity of this grading system. The intraobserver reliability between two surgeons was 86% and 77%, and the interobserver reliability was 68%. Although it is useful in determining the radiographic appearance of the HO, the Brooker classification does not address its functional effect.

OVERVIEW OF PREVENTION MODALITIES

HO prevention is based on preventing bone induction. The mainstays of this prevention are nonsteroidal anti-inflammatory agents (NSAIDs), ionizing radiation, and meticulous handling of surgical tissue.
The inhibitory action of NSAIDs on HO is probably related to their inhibition of the activity of prostaglandin synthetase. The resulting decrease in local concentrations of osteoactive prostaglandins may be key to the inhibition of formation of heterotopic bone. The change in environment tends to inhibit the proliferation and maturation of pluripotential osteogenic precursors and limits the development of heterotopic bone. Indomethacin has been shown in an animal model to be effective only if administered in the initial phase of bone induction (81). In studies of animals, NSAIDs have been shown to delay the healing of bone after local trauma. Rats that had been fed an aspirin-rich diet revealed a dose-dependent delay in fracture healing (41). Dahl (24) first reported on the use of indomethacin after total hip arthroplasty. Its use as an analgesic showed reduction of HO compared with the use of a placebo. Since that time, numerous studies have been conducted to compare the different anti-inflammatory agents with varying dosing and length of treatment. Because of the potential side effects of dyspepsia, bleeding, and inhibited bone healing, much emphasis has focused on finding the lowest dose and shortest length of treatment, without compromising the results of suppression of HO formation. Coumadin has been proven to be ineffective (103).

Numerous authors have investigated the use of radiation therapy. Most of their work centers around the use of such therapy after total hip replacement (23,25,43,47,48,61,58,71,74,78,86,106,107,127).

Careful handling of tissue during any surgical procedure, especially around the hip and elbow, is also of importance to minimize any trauma and subsequent inflammation. The role of proper surgical technique in the formation of heterotopic bone is difficult to quantitate.

Several unproved methods of prophylaxis have been studied. Riska and Michelsson (92) had encouraging results with the transplantation of fat after excision of HO, theorizing that filling the gap created in the soft tissues would prevent recurrence. Biphosphonates have been employed because they inhibit the transformation of amorphous calcium phosphate into hydroxyapatite and thereby the mineralization of osteoid matrix. Unfortunately, mineralization occurs when the medicine is discontinued. Thomas and Amstutz (120) found no difference when they compared biphosphonates to a placebo 2 years after the operation. Furthermore, the medication is expensive and can adversely affect calcium and phosphate metabolism, leading to conditions that include osteomalacia.

TOTAL HIP ARTHROPLASTY

HO is a frequent occurrence after a total hip arthroplasty (Fig. 124.1). Certain patients are at a higher risk for developing clinically significant HO: those with ankylosing spondylitis, osteoarthritis with large acetabular osteophytes, Forestier’s disease, Paget’s disease, bilateral disease, extensive operative trauma, formation of a hematoma, and those who have developed HO after a previous total hip arthroplasty. Men with osteoarthritis are at higher risk for HO than women (93). Ahrengart and Lindgren (3) concluded that men with osteoarthritis, men with fractures, women older than 65 with osteoarthritis, and women with hypertrophic osteoarthritis should be considered for prophylactic treatment.

The roentgenographic incidence of HO after cemented total hip arthroplasty without prophylactic treatment approximates 30%, with a reported range from 5% (21) to 90% (99) (Table 124.2). Of those who develop HO, 3% to 10% have pain and decreased range of motion as a direct result of the HO. Maloney and Krushell (72) found a significant increase in the severity of HO with uncemented total hip arthroplasty as compared with hybrid arthroplasty. The rate of clinically significant HO in cementless total hip arthroplasty is approximately 30% (68).

Table 124.2. Incidence of Heterotopic Ossification After Total Hip Arthroplasty

HO usually becomes visible on radiographs 3 to 4 weeks after operation and matures by 3 to 6 months. Histologically, HO is of the membranous type and has a woven structure that is later transformed into a more organized trabecular bone. Six months to 1 year after the operation, the rate of remodeling decreases, and the tissue tends to stabilize (Fig. 124.2).
**NSAIDs** Comparison of the effects of anti-inflammatory medications has been made in various studies with favorable results (Table 124.3) (33, 103). Schmidt et al. (103) found 6 weeks of indomethacin to be highly effective; a subsequent study by Knelles et al. (63a) showed 7 days to be adequate. Cella et al. (18) found that 30% of their patients could not be treated with indomethacin because of side effects. Indomethacin has been the drug of choice by many physicians, although a recent study found no difference between enteric-coated aspirin and indomethacin (69). Because of animal studies showing decreased bone healing after NSAID use, several authors have studied cementless total hip arthroplasty results. Kjaersgaard-Anderson et al. (62) reported that NSAIDs had no effect on the clinical results of cementless total hip arthroplasty.

**Radiation Therapy** The results of radiation therapy have been extensively studied (Table 124.4). Radiation therapy is delivered locally and not systemically. Ionizing radiation exerts its greatest influence on rapidly dividing cells by altering nuclear DNA. It is believed that radiation therapy prevents the differentiation of the pluripotent mesenchymal cells into osteoblastic stem cells (32). Radiation therapy may effectively block one of the earliest steps in a series of events leading to H.O. It is imperative to begin the therapy immediately to block the differentiation of stem cells, which peaks at 48 hours. It is delivered through anteroposterior portals centered on the prosthesis, which exposes the periacetabular tissue but not the surrounding radiosensitive organs.

</table>

Postoperative radiation therapy does not cause delayed wound healing or wound complications, providing that the incision is excluded from the field of irradiation. Trochanteric nonunion after radiation therapy in several studies of revision total hip arthroplasty ranged from 25% to 43%. This compares with the incidence of trochanteric nonunion in the absence of radiation of 2% to 15%. A comparison is difficult to make because the bone quality in revision total hip arthroplasty is usually poorer. Longo et al. (70) studied bone ingrowth in rabbits after porous prostheses with radiation therapy. The greatest delay of bony ingrowth was at 2 weeks, but by 6 weeks, the control group and irradiated groups were similar. No radiation therapy protocol has been discontinued because of patient intolerance, as has been reported with anti-inflammatory agents.

The risk of sarcoma after radiation therapy has been investigated by many authors. No soft-tissue sarcomas have been reported with less than 3000 cGy (12). Radiation in low doses has been associated with the development of leukemia (109). Although no definitive statement can be made regarding the risk of development of sarcoma after prophylaxis with radiation therapy, this possible side effect must be considered. The resistance of peripheral nerves to radiation, combined with low-dose techniques, has led to no documented cases of radiation-induced neuritis (74).

It is important to note that a single dose has a greater effect on tissue than fractionating doses. This greater tissue effect is referred to as the time-dose relationship (79). Table 124.5 shows a comparison of the time-dose fractionation (TDF) of various protocols.

**ACETABULAR FRACTURES**

HO is common after open reduction and internal fixation of acetabular fractures. It is seen in only about 5% of patients treated conservatively (67) but in as many as 90% after extensile approaches to acetabular fractures (68). Severe HO has been reported in approximately 24% of patients (56). Certain types of exposures, including the Kocher-Langenbeck, extended iliofemoral, and triradiate, have resulted in a high occurrence of HO, whereas the ilioinguinal exposure has not. The extended iliofemoral approach has the highest prevalence of HO (69). Postoperative HO prophylaxis is not required for fractures treated through the ilioinguinal exposure. Prophylaxis with either NSAIDs, single-dose local field radiation, or a combination should be used routinely early after open reduction and internal fixation with approaches other than the ilioinguinal approach. Moed and Letournel (78) reviewed 53 patients who underwent the posterior or extended iliofemoral approach and were treated with indomethacin and irradiation. Indomethacin was given for 3 weeks, and radiation therapy was given, either in divided or a single dose. Forty-four
fractures showed no HO, and 10 had grade I fractures. There was no difference between radiation doses.

ELBOW

From studies that have mostly focused on the hip, information about the incidence, pathophysiology, and treatment has been applied to the upper extremity. HO around the elbow is associated with local injury, electrical and thermal burns, and neurologic injury to the brain and spinal cord. The most frequent cause of heterotopic bone about the elbow is direct trauma (Fig. 124.3) (46). There appears to be a direct correlation between the frequency of HO and the magnitude of the injury. HO is usually seen in the collateral ligaments when it is associated with trauma.

Figure 124.3. A, B: Twenty-one-year-old patient with head injury resulting from attempted suicide, with signs of heterotopic bone formation bilaterally. C,D: HO following fracture and fixation of a distal humerus fracture.

HO develops in approximately 1% of patients who have sustained burns, 3% of patients with a local injury of the elbow, and 11% of patients with a head injury (36,88,121). The elbow is the most frequent site after a burn. When a fracture combined with a dislocation occurs, the incidence rises to 15% to 20%. The incidence of HO about the forearm is approximately 2% to 4%, with high-energy and open fractures most at risk. HO around the elbow, associated with head injury, has been investigated by Garland and O’Hollaren (38). The incidence of HO increases fifteenfold when the neurotraumatized patient has an associated elbow injury.

The Brooker classification is insufficiently sensitive to describe the functional loss of motion in the elbow (74). Hastings and Graham (46) divided HO in the elbow and forearm after all types of trauma into three classes (Table 124.6). A treatment plan should be based on severity of HO (Table 124.7).

Table 124.6. HO of Elbow and Forearm

| Class I | Radiologic evidence of heterotopic bone without functional deficit |
| Class II | Restriction of motion in either flexion/extension, pronation/supination, or both |
| Class IA | Limitation in elbow, flexor/extension plane |
| Class IB | Limitation in forearm, pronation/supination plane |
| Class IIA | Limitation in both planes of motion |

Table 124.7. Treatment Algorithm For Elbow Heterotopic Ossification

| Class I | Close observation, radiographs, physical therapy, e.g., arthroscopy, radiation therapy with or without NSAIDs, steroids, or physical therapy and MAID |
| Class IA | Surgery—heterotopic excision—improvement with radiation therapy, subsequent homologous collagen—improvement in range of motion, extension, supination, and flexion |
| Class IB | Radiation and physical therapy |
| Class IIA | Resection of a portion |
| Class IIB | Resection of a portion; excision of heterotopic bone |

Early range of motion is essential to prevent stiffness. Early after injury, there is no completely effective prophylaxis. The difficulty with the elbow is its smaller size, compared with the hip; therefore, a small amount of bone results in more functional limitations. Bridging bone in one plane is amenable to excision with good results, whereas synostosis in two or more planes has poorer results. Most surgeons wait 12 to 18 months before excision, with recurrence demonstrated frequently in patients (Table 124.7) (37,88,97). There is an advantage to early excision, particularly in those with neurologic injury. This allows for early rehabilitation, enhancing function and independence. In a recent review of eight patients who had excision of HO at an average of 7 months followed by radiation therapy, there was no recurrence and significant improvement in arc of motion (74). This compares with previous reports of recurrence rates up to 30% (37). Because the preoperative testing for maturation of HO is not reliable for recurrence, individualize the decision for excision.

The most common site for HO about the elbow is the posterolateral aspect of the elbow, from the olecranon to the lateral humeral condyle. The elbow can be approached by various incisions dictated by the location of HO (see Chapter 1). Postoperatively, early motion is imperative, with the continuous passive motion device used commonly. Initiate irradiation and anti-inflammatory medications within 72 hours of surgery.

TRAUMATIC HEAD INJURY AND SPINAL CORD INJURY

The complication of HO around the joints of patients was first described in patients with spinal cord injuries in the late 1800s, whereas its association with traumatic brain injury was first reported by Roberts in 1968 (86). The incidence of HO in adults who have had an injury to the brain ranges from 11% to 76% (100). Garland et al. (34,36,36 and 37) have studied the traumatic brain injury patient in depth. The frequency of HO in the upper extremity parallels that in the lower extremity. The incidence of HO in the shoulder is similar to that in the elbow (Fig. 124.4). Involvement of the upper extremities is more frequent in patients who have had injuries to the brain than in those with spinal cord injuries (34).
The incidence of HO in patients with spinal cord injury is reported to be 20% to 30% (34). Limitation of joint motion occurs in 18% to 37% of patients who develop HO (11,52). HO develops more often in patients with complete paralysis (102). Patients with spinal cord injuries usually present with HO anteromedial to the hip in the vicinity of the lesser trochanter, whereas in traumatic brain injury patients, the location is more variable. New bone formation in the head-injured patient is usually periarticular, whereas patients with spinal cord injury develop HO at a distance from the joint. Whereas the hip is the most common location for HO in neurologically injured patients, the elbow most often becomes ankylosed. New bone formation in the hip and elbow correlate with the position of the extremity. It is thought that diffuse axonal injury often produces spasticity, which is known to be associated with HO (1). Patients with spastic quadriplegia and those with low levels of recovery are particularly prone to the formation of HO and recurrence after resection.

The exact timing for resection is better defined when the lesion occurs after a spinal cord injury. Resection is usually performed when serial alkaline phosphatase and bone scan have returned to baseline. Brain-injured patients have a high variability of neurologic involvement and severity, as well as variability in anatomic location of HO. In a review of 23 patients with resection of HO in 37 joints, a recurrence of HO was found in 56%. The recurrence was closely linked to the severity of cognitive deficit and physical disability (37). Postoperatively, patients are irradiated or treated with NSAIDs. Biphosphonates are usually selected for prophylaxis if there is a contraindication to NSAIDs. The size of the initial HO mass may be the most important factor in predicting postoperative recurrence (118).

The site of the HO at the elbow or hip dictates the approach for resection. The shoulder is usually amenable to manipulation and only uncommonly requires resection. Most resections are carried out through a deltopectoral approach. The hip has three areas of possible development of new bone: anterior, inferomedial to the hip joint and distal to the lesser trochanter (associated with adductor spasticity), and posterior to the femoral head (associated with flexion contractures). The hip may be approached anteriorly or posteriorly.

CHARCOT'S NEUROARTHRPATHY

Neuropathic osteoarthropathy, or Charcot's disease, is a chronic form of a degenerative arthropathy that is associated with decreased sensory innervation. It results in fragmentation, destruction, and dislocation of the joints. Its most common locations are the knee, ankle, and foot joints (Fig. 124.5 and Fig. 124.6).

Eugene Martin Charcot, a French neurologist, first described neuropathic arthropathy in 1868 as a "trophic effect" in a patient with tabes dorsalis (20). He described a process of severe osteoarthritic changes, including swelling and instability of the knees. Prior to Charcot's description, Mitchell (77a) identified a destructive arthropathy associated with diseases involving peripheral nerves. Volkmann and then Virchow proposed that the underlying cause of the destruction was repeated traumatic events of varying degrees unrecognized by the insensitive joint. Steindler (44) was one of the first to link together the destructive atrophic form and the hypertrophic proliferative form, and to suggest that there were many types and degrees of the condition. Before the advent of antibiotics, syphilis was the most common cause involving primarily the knee. The first report of arthropathy associated with diabetes was by Jordan in 1936 (54), and even in 1966, the knee was still reported as the most common site (Table 124.8) (29).
Although there are many causes of Charcot's arthropathy, the three most common (in order) are diabetes, syphilis, and syringomyelia. There are approximately 10 million diabetics in the United States, with an incidence of Charcot arthropathy of 0.1% to 2.5% (77) usually occurring after 10 years of the disease. The most common diabetic complication requiring hospitalization is foot disease. There is equal prevalence in men and women and in type I and type II diabetes, and no correlation with glucose control. Those with concomitant renal disease have a higher risk of complications. Approximately 30% develop contralateral involvement (74). The incidence of HO associated with tabes dorsalis is 6% to 10%. The diabetic patient tends to have involvement of the tarsometatarsal joints, tarsal, and ankle joints, whereas in syphilitic patients, larger joints such as the knee are involved. The shoulder and elbow are affected most commonly in syringomyelia (Fig. 124.7).

### PATHOGENESIS

There are two theories of pathogenesis: neurotraumatic and neurovascular. The neurotraumatic theory proposed by Johnson in 1967 (63) involves repetitive trauma sustained by a joint unable to sense pain. In cats, a denervated immobilized limb does not produce a destructive arthropathy, but it can occur when the cats are allowed to freely walk (58). This does not account for the sensation of pain and neuroarthropathic changes that can occur after acute fractures. It also does not explain the gross destruction of joints that do not bear weight.

The neurovascular theory, suggested by Allman and Brower (5), refers to a sympathetic dysfunction with persistent hyperemia and active bone resorption by osteoclasts. As early as 1927, Lerche noted that lesions of the sympathetic nerve led to an increase in blood flow (5). Blood flow may actually increase up to five times the normal rate in diabetic neuropathy.

Joint destruction in the neuropathic joint is probably brought on by a combination of factors that include damage to the nociceptors of the joint and the periaricular tissues. This injury may initially be caused by mechanical trauma, chronic infections such as syphilis, or metabolic diseases such as diabetes associated with loss of pain and proprioception. This leads to stretched ligaments, and lax and subluxed joints. The activity of peptides such as substance P, calcium gene–related peptide, and vasoactive intestinal peptide (VIP) could result in increased vascularity and inflammation, contributing to further joint destruction. Substance P can enhance the cellular synthesis of collagenase and prostaglandin-E, activate T lymphocytes, monocytes, and neutrophils; and take an active part in inflammation. Glycolization of the supporting ligaments in the foot due to high glucose levels in the blood can increase the stiffness and cross-linking of the collagen fibers, making them brittle.

The initial pathologic changes occur in the underlying bone and cartilage. Recurrent effusions occur due to hyperplasia of the synovium. The articular cartilage is slowly destroyed by a pannus, which helps distinguish Charcot's joints from other forms of osteoarthrosis. Histology of the fragments of cartilage and bone in synovium shows deeply embedded tissue with normal metachromatic staining. In contrast, in osteoarthrosis the fragments are deposited superficially and have staining characteristics suggestive of degeneration (68).

Excess osteoclast activity is believed to be responsible for the early bone changes associated with Charcot's neuroarthropathy in diabetes mellitus. In a recent study by Gough et al. (41) the serum carboxyterminal telopeptide of type 1 collagen, a marker of osteoclastic bone resorption, had significantly increased levels in the acute Charcot foot. The lack of an associated increase in osteoblastic activity supports the idea that excess osteoclast activity is a feature of the early stages of Charcot's neuroarthropathy.

High-peak plantar pressures have been identified as a risk factor for ulceration in diabetics. In a study of 164 diabetic patients, higher peak plantar pressures occurred in those with Charcot's arthropathy and those with neuropathic ulcers than in those without. Measuring plantar pressures might be an effective means of screening large numbers of patients (8).

### CLINICAL PRESENTATION

The most common presentation of neuroarthropathy in a diabetic patient is a single, painless, swollen, deformed foot and no specific history of trauma. The joint has a large effusion, ligamentous laxity, and increased warmth, but the peripheral white blood count (WBC) and the ESR are normal. The swelling and warmth may suggest an infection or pseudoseptic arthritis. The synovial fluid is clear, straw colored, and viscous, although it can be bloody. Usually, there is evidence of peripheral neuropathy in the presence of normal or bounding pulses. Joint changes frequently precede the neurologic deficit, and as many as one third of patients actually have pain at presentation (57). The deep tendon reflexes at the knee are absent in a majority of patients. Some patients present with nontraumatic dislocations or rapid joint destruction without any known trauma. The spine is involved in 6% to 21% of cases (40). Anand et al. (7) reported on a patient with neuropathic spinal arthropathy in Charcot-Marie-Tooth disease. Nonspiral fractures of the long bones should heighten concern, because considerable force would normally be necessary to cause such an injury. Rule out other disease processes such as avascular necrosis (AVN), infection, crystal-induced arthrosis, hemophilia, and rheumatoid arthritis (RA).

### IMAGING

Early radiographs may demonstrate changes very similar to those observed in early osteoarthrosis. Nontraumatic dislocations may be an early sign. With time, there is radiographic evidence of joint distention caused by fluid, hypertrophic synovitis, osteophytes, and subluxation. The normal architecture of the joint is lost, with dislocation, fragmentation, attempted repair by osteophytes, and sclerosis. Various degrees of bone absorption have been observed, with margins resembling surgical amputation coupled with periaricular speckled calcification in the soft tissue. Infection usually produces indistinct margins of bone as opposed to the sharp ones seen in neuroarthropathy.

Osteomyelitis typically is secondary to infected ulcers or cellulitis, with direct infectious spread to and through the cortex of the adjacent bone. Establishing the diagnosis of osteomyelitis in the foot may be difficult (see Chapter 116). Use imaging studies to confirm the clinical suspicion of osteomyelitis. Lipman et al. (67) studied the diagnostic efficacy of combined three-phase bone scintigraphy and indium-111–labeled WBC scintigraphy, magnetic resonance imaging (MRI), and conventional
radiography in detecting osteomyelitis of the neuropathic foot. MRI was found to be comparable to conventional radiography. In the midfoot and hindfoot, three-phase or WBC scans were more specific than either MRI or conventional radiography. MRI was most accurate in the forefoot.

FOOT AND ANKLE

Classification and Staging

The staging of neuroarthropathy according to Eichenholtz (29) uses both clinical and radiologic criteria. Stage I consists of an acute, warm, swollen, erythematous foot. Radiographic changes of bony fragmentation may occur and are often confused with osteomyelitis. Stage II involves the beginning of the subacute process, in which swelling subsides and new bone formation occurs. Stage III is chronic; in it, the foot no longer is warm and swollen but is severely deformed. Schon and Marks (105) have added a stage 0: the diabetic patient at risk for neuroarthropathy after an injury.

Brodsky (13) has developed a classification of neuroarthropathic joints that allows for recognition of potential problems as well as helping to establish the prognosis after treatment.

- Type I neuropathy shows midfoot manifestations in 60% to 70% of cases. It is characterized by symptomatic medial and planter bony prominences that may lead to ulceration. A substantial indirect bending force is applied to the ankle during the midstance and terminal-stance phases of gait.
- Type II involves the hindfoot, representing 20% of Charcot's joints; it is characterized by instability and requires long periods of immobilization.
- Patients with type IIIA neuropathy have an incidence of less than 10%. This type includes ankle injuries, and are the most unstable and take the longest time to heal.
- Type IIB involves the os calcis, which presents clinically as a pathologic fracture of the tuberosity of the calcaneus. These patients risk progressive pes planus and tendo-Achilles incompetence. The Wagner classification (128) focuses on the progression of involvement of the soft tissue, which leads to eventual extension into the bone midjoints.

Treatment

The goal of treatment is to restore a biomechanically sound, plantigrade foot. The treatment of the injury should depend on the timing, the stage of the injury, and the objective findings in the physical exam. A choice must be made between conservative and operative treatment based on the overall clinical scenario (Table 124.9). Education of the patient on the importance of foot care is of paramount importance. Successful treatment results in a braceable ankle without ulceration. The midfoot is afflicated most severely, followed by the hindfoot and the ankle. Midfoot Charcot's joints tend to become more stable over time, in contrast to the hindfoot and ankle joint, which become painful and prone to ulceration. Total-contact casts are helpful in the management of the ulcers, with 86% of them healing within 2 years (69).

Most authors agree that immobilization in plaster is the mainstay in managing this condition in the early stages of the disease process. Immobilization has been proven to slow down and sometimes arrest destruction (28). Early stability helps prevent bony prominences from causing ulceration. The length of immobilization varies with the clinical exam. Saltzman et al. (100) found that a properly fitted patellar tendon-bearing (PTB) brace can reduce load transmission to the Charcot hindfoot. Selby et al. (109) showed that bisphosphonates can produce prompt reduction in the Charcot activity. Ultrasound has been successful in the treatment of 28 of 29 patients with Charcot's neuropathy of the foot and ankle (64). There are many who recommend protected weight bearing of the contralateral uninvolved foot and ankle (69). Some patients develop deformity despite proper treatment or present with significant deformity. This is especially true of patients who have a varus or valgus deformity associated with involvement of the ankle or subtalar joint. The foot is at risk for recurrent ulceration and infection.

Treat patients presenting with Eichenholtz I findings with serial-contact casting and avoidance of weight bearing until the acute edema has resolved. Surgery can be considered for severe dislocation that is unstable and manually reducible. Bone fragmentation is a contraindication for surgery.

Once the edema has resolved and the patient shows early healing (stage II), allow progressive weight bearing. Replace the cast with a brace once healing occurs. Johnson (53) has shown that bracing is frequently effective in the treatment of the deformed neuropathic foot. Bracing for ankle, hindfoot, and midfoot may include a Charcot restraint orthotic walker, a double upright metal foot orthosis, or a modified ankle-foot orthosis. The forefoot can be managed with well-padded total-contact inserts.

Once the patient progresses to a chronic stage or Eichenholtz III, he or she can be managed in a long-term brace or with continued use of the shoe insert. If the patient regresses back to the acute stage, he or she must be placed into a total-contact cast and weight bearing must be restricted. Bracing is successful in arresting the deformity and providing a stable ankle-foot complex, and it is the treatment of choice. It is imperative to evaluate the skin and soft tissues at regular intervals for evidence of breakdown. Once the deformity continues to progress with weight bearing, the soft tissues overlying the bone may begin to break down. Although the ulceration and infection can be treated with local wound care and antibiotics, the underlying cause is the deformity. With continued use of the extremity, a cycle of breakdown and infection occurs. Bracing and foot and ankle appliances are frequently not effective at this point. The deformed limb ceases to be functional and requires surgery.

In a series of 221 neuropathic fractures, Schon et al. (104) noted that nondisplaced neuropathic ankle fractures typically healed uneventfully with casting and bracing. Closed reduction and casting for displaced fractures has often resulted in loss of reduction and progressive deterioration. Open reduction and internal fixation provides better results (129). Fracture stability may be enhanced by multiple syndesmotic screws.

Excellent surgical technique and prolonged immobilization are essential for proper fracture management. Connelly and Csencsiz (22) reported on six ankle fractures in five patients with longstanding diabetes. One patient needed an amputation 10 days after a closed injury, stressing that significant complications can occur.

Ankle fusion is difficult to achieve in Charcot's disease because of the poor quality of the bone and the difficulty in achieving a stable biomechanical construct with screws, plates, or external fixation. The plantigrade foot with the ankle at 90°, the hindfoot in 5° to 10° of valgus angulation, and external rotation of the foot with the foot in equinus to that of the contralateral foot (85). Results of surgery have varied between series. Bono et al. (11a) performed 11 arthrodesis procedures for Charcot's joint and achieved clinical union with good stability in 91%. Papa et al. (85) reported a 93% clinical success rate despite a 31% pseudarthrosis rate. Stuart and Morrey (117) reported on ankle arthrodesis procedures on 13 patients, with clinical union in seven patients. Pinzur and Kelkian (89) reported on the stabilization of patients with a retrograde intramedullary locked nail that had failed rigorous nonoperative measures. Nineteen of 21 ankles progressed to fusion at an average of 20 months.

When the talus is fragmented and avascular, perform a takedown and a tibiocalcaneal arthrodesis. Consider ankle disarticulation (Symes amputation) before ankle fusion in the most severe cases to avoid progression to a more proximal amputation in the future. Postoperatively, do not allow weight bearing. Observe the patient closely for postoperative complications such as ulceration, infection, and pseudarthrosis.

The midfoot sometimes continues to progress with ulceration and deformity despite casting, bracing, and shoe modifications. Exostectomy is most effective in the chronic, midfoot deformity that is stable. If the foot is unstable, realignment and arthrodesis is the procedure of choice. Early and Hansen (27) reported on 21 patients with fusions who had midfoot collapse. Despite 50% postoperative complications and two amputations, 86% of patients had successful results.

Table 124.9. Wagner Classification of Neuropathic Ulcerations (128)
The standard of care for hindfoot neuroarthropathy is nonsurgical. Harris and Brand (45) and Johnson (53) advocate immobilization in plaster. Consider arthrodesis for hindfoot valgus with subluxation of the subtalar joint or midtarsals to prevent ulceration and infection. Täsel et al. (122a) reported on eight triple arthrodeses in seven patients with 100% union for peritalar neuroarthropathy. They stressed the principles outlined by Papa et al. (85):

- Careful removal of cartilage and debris.
- Thorough removal of sclerotic bone.
- Adequate fashioning of congruent bone surfaces for apposition.
- Rigid fixation of the arthrodesis site.
- Complete resection of fibrotic capsular tissue and synovium.

Amputation eliminates the immediate problem, but most patients develop limitation of function that necessitates a modification of their lifestyle (58). There is an increased energy requirement to walk after amputation, which can be a problem in diabetics with other comorbid conditions. There is also a risk of an amputation on the contralateral limb, so limb salvage should be attempted whenever possible.

**HIP**

Charcot neuroarthropathy in the hip is rare. As with any joint, the critical element in treating a patient with a neuropathic hip joint is to establish the diagnosis (Fig. 124.8) (6).

![Figure 124.8. AP hip demonstrating Charcot's arthropathy.](image)

If the joint remains painless and functional, no intervention is required. If pain is present and function is impaired, pursue conservative treatment with protected weight bearing as long as possible before considering any type of surgical procedure. Treatment with hip arthrodesis results in a high rate of nonunion; historically, it has been as high as 100% (53). Total hip arthroplasty also has a high failure rate, especially in patients with significant neurologic findings or ataxia. The overwhelming evidence in the literature is that these patients do poorly with any type of prosthetic replacement. The number of patients treated with total hip arthroplasty reported in the literature is small, reflecting the relatively low incidence of neuropathic hips. They have universally done poorly (63, 114). This limited evidence strongly indicates that prosthetic replacement of the Charcot hip joint is contraindicated. Of the dozen or so cases reported in the literature, only one patient was stated to have done well with a total hip joint arthroplasty (114). The remainder did poorly even when treated with a broad range of total hip designs. Resorting to a resection arthroplasty may be the only viable solution in the treatment of the painful hip in these patients.

The treatment of hip fractures in a Charcot hip joint also remains problematic. Johnson (53) found that over 50% of fractures of the femoral neck in diabetics developed Charcot's joints. Many times, the neurosurgical nature of this fracture is not recognized, and hip nailing or a prosthesis is inserted, only to result in failure. Internal fixation has been documented to do as poorly as prosthetic replacements. Treatment with restricted weight bearing may be the most prudent option with a delayed resection arthroplasty if the joint subsequently becomes painful.

Complex fractures of the acetabulum in patients with diabetes are difficult to treat. Berg (10) reported on three patients who developed Charcot's changes after open reduction internal fixation for fractures of the acetabulum. None had any previous evidence of a neuropathy.

**KNEE**

Charcot's neuroarthropathy in the knee has previously been reported as the most common neuropathic joint problem secondary to syphilis and one of the most difficult to treat (53). There is tremendous leverage, predisposing to instability, and little soft-tissue envelope to cushion the joint. When the knee is painless, bracing is the treatment of choice. Johnson (53) recommends a corrective osteotomy to prevent shearing stress, followed by bracing for severely damaged knees, particularly with bilateral involvement. If only one knee is involved and destruction is severe, fusion is indicated. Bracing is imperative to promote a solid union.

Fractures in diabetics are best treated by prolonged immobilization and splinting until there is definite radiographic evidence of repair. The potential for complications with immobilization is high. Arthrodesis, usually the treatment of choice in advanced disease of the knee, may fail because of nonunion and breakage of fixation devices. Drennan (26) found a 55% clinically successful arthrodesis in his series of patients with knee fusion. Arthroplasty is generally considered contraindicated in Charcot's joints. Loosening and breakage of the prosthesis is more likely to occur secondary to lack of proprioception, although the results of nine total knee arthroplasties were considered excellent in eight knees after a 3-year follow-up (113). Correct ligamentous balancing, use of long-stemmed components, and meticulous surgical detail are imperative for good long-term results. Despite these good reported early results, total knee arthroplasty should be approached in these patients with great caution because the long-term results undoubtedly will not be as favorable.

**AUTHORS' PERSPECTIVE**

Both HO and Charcot's neuroarthropathy represent distinct, potentially devastating pathologic conditions affecting joints. Although the two problems are different, the key to the successful treatment and outcome of each is early recognition of patients at risk and taking the appropriate preventive measures. Once the conditions have been established, their outcomes, regardless of treatment, are less favorable.

Osteonecrosis, also referred to as avascular necrosis (AVN), aseptic necrosis, and ischemic necrosis, is not a specific disease but rather a condition in which a circumferential area of bone becomes necrotic as a result of a loss of its blood supply. The femoral head is the site most often affected, and the most frequent cause is a displaced fracture through the femoral neck. Posttraumatic osteonecrosis is best dealt with in a section on fractures; therefore, this chapter focuses on nontraumatic osteonecrosis of the adult hip. It also includes a brief description of other areas that may be involved.

In 1962, Mankin and Brower (73) reported five new cases of bilateral idiopathic osteonecrosis of the hip and stated that only 22 additional cases could be found in the English literature. Since that time, this diagnosis has been made with increasing frequency because of both an increased incidence and improved methods of diagnosis. It is currently estimated that 15,000 to 20,000 new cases are diagnosed annually in the United States alone and that osteonecrosis accounts for approximately 10% of the total hip replacements (THRs) performed.

Despite growing interest in this condition, there is much yet to learn about its etiology, pathogenesis, and treatment. A number of etiologic factors have been implicated, although the exact mechanisms by which they act have not been completely determined. The most commonly identified are high doses of corticosteroids and chronic, excessive alcohol intake. In most series, approximately 15% of the cases are considered to be idiopathic; however, as we learn more about etiologic factors, the number of patients placed in this category will diminish. For example, it has recently been shown that in approximately 70% of “idiopathic” cases, subtle coagulopathies are present (47). The clinical picture is nonspecific. The presenting symptom is usually unilateral hip pain, which may be followed by a limp and a decreased range of motion (ROM). Young adults between the ages of 30 and 40 are most frequently affected, and the condition is bilateral in more than 50% of patients. Diagnosis is usually made from plain radiographs, but in the earlier, asymptomatic stages, magnetic resonance imaging (MRI) may be required.

Although we have improved our ability to diagnose osteonecrosis early, we still do not have completely satisfactory methods for treating this condition. Our goal is to preserve and not replace the femoral head. A number of procedures have been described to accomplish this. Although an accurate comparison of their relative effectivenesses is not yet available, surgical treatment of osteonecrosis in general yields better results than protected weight bearing and symptomatic management. Whichever procedure is selected, a better outcome will be achieved if the condition is diagnosed and treated early, well before femoral head collapse. Patients with advanced stages of osteonecrosis are generally treated symptomatically until such time as hip arthroplasty or other reconstruction is indicated.

ETIOLOGY, PATHOPHYSIOLOGY, AND PATHOGENESIS

ETIOLOGY

Because of the limited biological response of different organ systems, various etiologic factors can lead to similar pathologic changes. In most cases of osteonecrosis, a specific etiologic factor or factors can be identified. In traumatic cases such as hip dislocation and femoral neck fracture, there is a clear cause-and-effect relationship between the insult, mechanical damage to the vessels that supply the femoral head, and the resulting osteonecrosis. A number of etiologic factors can be identified in patients with nontraumatic osteonecrosis. These include intraosseous narrow displacement disorders that lead to increased pressure in the femoral head and neck, such as Gaucher’s disease, leukemia, and myeloproliferative disorders (52,58,85,144). Other conditions, such as radiation and chemotherapy, lead to bone necrosis by direct cell toxicity. Mechanical blockage of vessels may be caused by emboli composed of abnormal red blood cells, such as in sickle cell disease and thalassemia; or nitrogen bubble emboli, such as in caisson disease, or dysbarism (69,60).

In many cases of osteonecrosis, the etiology is less clear. In these cases, one can often identify specific factors known to be frequently associated with osteonecrosis, although the exact mechanisms by which they act have not been completely delineated (Table 125.1). For example, high doses of corticosteroids and excessive alcohol intake have been identified in nearly 80% of cases of nontraumatic osteonecrosis (30,52,53,61,84,85,87,144). However, a one-to-one relationship between these factors and this disorder has not been established, because most patients exposed to steroids or alcohol do not develop osteonecrosis (30,84,85). Although the entity of idiopathic osteonecrosis most likely does exist, as we learn more about the etiology of this condition, the number of patients who will be relegated to this
related to emboli composed of clumps of abnormal red blood cells or to nitrogen bubbles, which can lodge within vessels and can also accumulate in the fatty marrow

Sickle Cell Disease and Dysbarism

edema in the pathogenesis of osteonecrosis remains unclear (18). Thus, the role of marrow

Elevated Bone Marrow Pressure Several investigators have found elevated bone marrow pressures and abnormal stress tests in hips with osteonecrosis (52, 144). Core biopsy specimens from patients with early stages of osteonecrosis have shown histologic changes taking place in the marrow before bony abnormalities appear (1, 11). This observation has led to the theory that the bone acts like a Starling resistor (52), in which thin-walled vessels traverse the space within a rigid outer cortex. Any increase in the pressure within this compartment would tend to cause the vessel walls to collapse, thus leading to decreased blood flow. Although it is well established that increased intraosseous pressure is present in and around areas of osteonecrosis, it is uncertain whether this is an initial event causing the osteonecrosis or whether it takes place after some other etiologic factor and then contributes to the pathogenesis.

Cellular Hypertrophy and Marrow Infiltration Since marrow elements and trabeculae of cancellous bone exist within a closed compartment made up of cortical bone, it is possible that hypertrophy of fat cells and infiltration of the marrow within this compartment can cause an occlusion of vessels and place abnormal pressure on osteocytes and marrow cells. There are several circumstances in which this might be implicated in the pathogenesis of the ischemia: (a) corticosteroid therapy, (b) Gaucher's disease, (c) leukemia, or (d) caisson disease or dysbarism.

Bone Marrow Edema Intraosseous edema is a finding common to osteonecrosis. This has been documented histologically and by MRI (85). However, edema can occur without the subsequent development of osteonecrosis, as noted in transient osteoporosis of the hip or bone marrow edema syndrome. Thus, the role of marrow edema in the pathogenesis of osteonecrosis remains unclear (18).

Intraosseous Intravascular

Sickle Cell Disease and Dysbarism A strong association exists between osteonecrosis and both sickle cell disease and dysbarism (59, 60). This is believed to be related to emboli composed of clumps of abnormal red blood cells or to nitrogen bubbles, which can lodge within vessels and can also accumulate in the fatty marrow

Table 125.2. Pathogenic Mechanisms

Direct Cellular Toxicity Exposure to radiation, chemotherapy, or thermal injuries can cause injury to and death of marrow cells and osteocytes and lead to osteonecrosis of the femoral head. It has been proposed that corticosteroids and alcohol have direct cytotoxicity; however, in vitro studies have indicated no direct cytotoxic effect with alcohol at physiologically tolerated concentrations. In certain animal studies, fat accumulation in the marrow and within osteocytes after exposure to corticosteroids has been implicated as a cause of bone cell death; however, no animal model has developed the collapse that is characteristic of the human disease (59, 80, 141).

Extravascular Venous Osteonecrosis that occurs after femoral neck fractures and hip dislocation is a direct result of injury to the arteries and veins that supply a significant portion of the femoral head. Angiographic studies in cases of nontraumatic osteonecrosis have demonstrated a high incidence of abnormalities in major vessels about the hip, including the retinacular arteries (14, 15). Superselective microangiographic studies of preclinical and contralateral “normal” hips have been consistent with a diagnosis of intraosseous vascular occlusion (113). Osteonecrosis may be encountered after various surgical procedures about the hip, as well as after forceful manipulation and casting in extreme positions. These are related to iatrogenic trauma to regional vessels.

Extravascular Arterial

Osteonecrosis may be encountered after various surgical procedures about the hip, as well as after forceful manipulation and casting in extreme positions. These are related to iatrogenic trauma to regional vessels.

Extravascular Arterial

Hemorrhage Paul Ficat (52) observed the presence of intramedullary hemorrhage in the osteonecrotic lesion of core biopsy specimens. Saito et al. (103, 104) also reported evidence of old hemorrhage in areas of necrosis without microfractures. Using a rabbit model of hypersensitivity vasculitis, one study (141) found that in 7 of 20 animals that were injected with both horse serum and methylprednisolone acetate, there was histologic evidence of vascular lesions and fresh intramedullary hemorrhages. Perfusion studies have demonstrated narrowing and a decrease in the number of vessels supplying the femoral head with formation of fine new anastomotic arterioles around areas of infarct in the bone of transplant patients treated with corticosteroids (112). Saito et al. (103, 104) found areas of fresh hemorrhage in association with arterial damage adjacent to microfractures and necrotic trabeculae. They concluded that multiphasic episodes of intramedullary hemorrhages are an important element in the pathogenesis of osteonecrosis. However, other investigators have proposed that the necrotic lesions resulted from a single rather than multiple events.

Elevated Bone Marrow Pressure Several investigators have found elevated bone marrow pressures and abnormal stress tests in hips with osteonecrosis (52, 144). Core biopsy specimens from patients with early stages of osteonecrosis have shown histologic changes taking place in the marrow before bony abnormalities appear (1, 11). This observation has led to the theory that the bone acts like a Starling resistor (52), in which thin-walled vessels traverse the space within a rigid outer cortex. Any increase in the pressure within this compartment would tend to cause the vessel walls to collapse, thus leading to decreased blood flow. Although it is well established that increased intraosseous pressure is present in and around areas of osteonecrosis, it is uncertain whether this is an initial event causing the osteonecrosis or whether it takes place after some other etiologic factor and then contributes to the pathogenesis.

Cellular Hypertrophy and Marrow Infiltration Since marrow elements and trabeculae of cancellous bone exist within a closed compartment made up of cortical bone, it is possible that hypertrophy of fat cells and infiltration of the marrow within this compartment can cause an occlusion of vessels and place abnormal pressure on osteocytes and marrow cells. There are several circumstances in which this might be implicated in the pathogenesis of the ischemia: (a) corticosteroid therapy, (b) Gaucher's disease, (c) leukemia, or (d) caisson disease or dysbarism.

Bone Marrow Edema Intraosseous edema is a finding common to osteonecrosis. This has been documented histologically and by MRI (85). However, edema can occur without the subsequent development of osteonecrosis, as noted in transient osteoporosis of the hip or bone marrow edema syndrome. Thus, the role of marrow edema in the pathogenesis of osteonecrosis remains unclear (18).

Intraosseous Intravascular
Lipid Emboli

Emboli of intravascular fat have been proposed as another etiologic factor that may lead to osteonecrosis (65,69). The association of hyperlipidemia with gout, alcoholism, and corticosteroid therapy is believed by some to support this hypothesis.

Thrombosis and Coagulation Disorders

With the development of more sophisticated laboratory tests, the possibility that hypofibrinolysis and thrombophilia may play roles in the pathogenesis of osteonecrosis has gained support (38,45,87,138). In thrombophilia, there is an increased tendency to form intravascular thrombi, whereas in hypofibrinolysis, thrombi that have already formed are less readily lysed and removed. Abnormal levels of the specific factors associated with these conditions have been documented in more than 70% of patients with osteonecrosis—in those previously diagnosed as having “idiopathic” osteonecrosis as well as in those in whom other predisposing factors have been identified. However, as is the case for other etiologic factors, not all individuals with these abnormalities develop osteonecrosis.

These can be autosomal dominant disorders and a high familial incidence has been demonstrated. It may therefore be possible to detect patients at risk before osteonecrosis develops. Because these disorders can in part be reversed by the use of anticoagulants, a pharmacologic treatment might theoretically be effective both in preventing the development of osteonecrosis and in lessening its severity once it has occurred. Therefore, consider testing for these abnormalities in patients with clinically diagnosed osteonecrosis and in their close relatives as described in the later section, “Laboratory Tests.” A consultation with a hematologist might be indicated in certain cases.

Hypersensitivity Reactions

Recently, it has been suggested that intravascular coagulation might be a result of pathophysiologic mechanisms such as the Schwartzman phenomenon, in which immune complex deposition may lead to vascular damage and ultimately osteonecrosis. Several animal models have been developed that demonstrate this phenomenon. When corticosteroids were added, bone necrosis can be produced. However, the overall picture was quite different from osteonecrosis as it occurs in humans, and there is no proof that this mechanism plays a clinical role in the development of the human disorder.

Multifactorial Etiology

Osteonecrosis may be multifactorial in etiology—that is, not one but several precipitating factors may act simultaneously or in sequence (64). There are several ways this can develop. For example, a patient may have an underlying abnormality, such as a subtle coagulation defect, but may not develop osteonecrosis until one or more additional factors are present. These might include excessive alcohol intake or chronic steroid administration. Under other circumstances, a specific etiology factor may evoke more than a single mechanism to cause vascular injury. For example, excess corticosteroid use can cause hyperlipidemias that result in intravascular lipid emboli. These in turn cause intravascular coagulation. In addition, steroids may cause direct cellular toxicity and may lead to abnormalities in marrow fat, thus causing increased pressure on local vessels. In addition to the factors identified to date, it is quite possible that other factors that predispose patients to the development of osteonecrosis have yet to be identified.

PATHOGENESIS

Although several different etiologic factors can lead to vascular impairment in osteonecrosis, the sequence of events that follow the initial insult or insults is similar. The resultant hypoxia rapidly leads to increased cell membrane permeability, which allows fluid and electrolytes to enter the cell, causing it to swell. Intracellular lysosomal enzymes are released, resulting in autodigestion or coagulation necrosis and cell rupture. Vascular injury leads to tissue edema and hemorrhage. An inflammatory response ensues, marked by the appearance of neutrophils and macrophages.

Death of bone is more difficult to diagnose than marrow necrosis and is predicated on the disappearance of osteocytes from within their lacunae, a process that takes several days to develop (Fig. 125.1). The center of the necrotic lesion remains avascular and repair is not possible. Bone and soft-tissue detritus accumulate. As a result of repeated stresses, dead trabeculae undergo microfractures that cannot be repaired.

Figure 125.1. Necrotic bone and marrow from the center of the ischemic area (hematoxylin and eosin, ×50).

Toward the periphery of the necrotic area where sufficient vascularity is present, the transition zone, an active process of repair begins. Macrophages and osteoclasts remove dead marrow elements and bone. Granulation and fibrous tissue are formed. Osteoblasts form new bone, much of which is laid down directly on remnants of dead trabeculae (Fig. 125.2). The resulting trabeculae are much thicker than normal and are responsible for the sclerotic margin that surrounds the lesion and that is one of the radiographic hallmarks of osteonecrosis (Fig. 125.3).

Figure 125.2. Tissue taken from the periphery of the lesion (transition zone) shows active bone resorption and formation, and the presence of macrophages, lymphocytes, and fibrous tissue (hematoxylin and eosin, ×100).
If the lesion is small, and particularly if it is not in a major weight-bearing region of the femoral head, it may undergo revascularization and be completely replaced with viable bone. Alternatively, it may remain as a small sequestrum surrounded by a wall of new bone. In either case, femoral head collapse does not occur, the hip continues to function normally, and the patient remains asymptomatic.

Larger lesions, particularly those in a region of major weight bearing, have a poor prognosis. The attempt at repair is only partially effective. Bone resorption is more rapid than formation. There is a gradual collapse of cancellous bone beneath the bony endplate of the weight-bearing aspect of the femoral head. If the contour of the articular surface remains intact, a fluid-filled space beneath the cortical subchondral bone develops, which gives the appearance of a crescent sign on radiographs (Fig. 125.4). With flattening and collapse of the articular surface, this space is obliterated and the crescent disappears. Gross flattening of the femoral head is now apparent (Figs. 125.5).

Articular cartilage derives its nourishment from synovial fluid within the joint rather than from vessels in the cancellous bone, so it remains viable while the attached subchondral bone dies. The mechanical stresses on the collapsed and irregular articular surface eventually result in damage to and death of chondrocytes (Fig. 125.6). These abnormal stresses are transferred to the otherwise normal cartilage of the acetabulum, which undergoes secondary degenerative changes. Joint line narrowing becomes obvious on radiographs. As the processes of degeneration continue, the underlying acetabular bone becomes affected. Typical changes of degenerative joint disease appear and include sclerosis, cyst formation, and marginal osteophytes. End-stage arthritis of the hip eventually ensues (18,28,55,56,76,113,114).

TRANIENT OSTEOPOROSIS OF THE HIP

Osteonecrosis is quite different histologically from transient osteoporosis (or osteopenia) of the hip (TOH) (39,42), although these two conditions can be confused. In TOH, there are no findings of bone infarction or repair, which are the hallmarks of osteonecrosis. The pathologic picture is primarily one of marrow edema, hence TOH is also referred to as bone marrow edema syndrome (BMES). Some of the pathologic features of TOH, such as the presence of edema fluid, have also been found in early stages of osteonecrosis, and this has led some authors to conclude that these two entities are at different ends of the spectrum of the same disorder (49).

Clinically, transient osteoporosis also behaves differently from osteonecrosis. The onset of pain is usually more sudden and it is often more severe. To minimize the chance of fracture, place patients on crutches until there is clinical, radiographic, and MRI evidence of resolution. This may require 4–6 months. This condition affects men more often than women, and these patients have no associated risk factors as in osteonecrosis. In women, it classically develops during the third trimester of pregnancy, and the incidence of fracture is greater than in men. The disease rarely involves both hips at the same time. Occasionally, the opposite hip is affected months or years later. It is difficult to make a definitive diagnosis on the basis of standard radiographs because the only abnormality is mild osteopenia of the femoral head and neck. However, the diagnosis can be made readily based on MRI in most cases.

It is essential to distinguish transient osteoporosis from osteonecrosis, because the natural histories, prognoses, and treatments of these two conditions are quite different. Because TOH is usually self-limited, it is treated with protected weight bearing to prevent fracture. Infrequently, core decompression may be indicated if a patient has an inordinate amount of pain or if the diagnosis is in doubt. Osteonecrosis, on the other hand, is a progressive disorder if untreated, and in most instances early diagnosis and treatment are required (18,48,49).
EARLY DIAGNOSIS

The diagnosis of established osteonecrosis of the femoral head is usually not difficult because the radiographic picture is often pathognomonic. Our goal, however, is to make the diagnosis as early as possible, ideally before characteristic changes appear on radiographs. This will allow early treatment with procedures that may help retard or reverse progression of this condition and save the femoral head. This, in turn, requires a familiarity with its etiology, pathogenesis, and clinical features, as well as with the laboratory tests and imaging studies that enable us to make the diagnosis early.

CLINICAL FEATURES

The signs and symptoms of osteonecrosis are nonspecific. For weeks and perhaps even months after the initial vascular insult, the involved area may be entirely asymptomatic. When symptoms develop, they usually do so gradually. This may be due to a buildup of intraosseous pressure initially and later perhaps to microfractures of affected trabeculae. The pain is usually localized to the inguinal region but may involve the buttock or the upper thigh. Rarely does it radiate as far as the knee. It may be present at rest but is often exacerbated by activity. Later, a limp and a slight decrease in ROM, associated with pain, may develop.

Although both hips are affected in more than 50% of the cases, the involvement is usually not simultaneous. Therefore, the patient will normally present initially with symptoms on only one side. If the contralateral hip is affected, symptoms will usually develop within 3 to 6 months. Approximately 80% of asymptomatic hips with MRI-proven osteonecrosis eventually become symptomatic. The incidence is much less in the case of small lesions. When the asymptomatic contralateral hip of a patient with osteonecrosis on the opposite side appears normal on the initial MRI, there is less than a 10% incidence that this hip will develop osteonecrosis at a later date (32). In a small number of cases of advanced osteonecrosis, the patient may develop a positive Trendelenburg sign and have shortening of the limb, due both to collapse of the femoral head and to a limited range of hip motion resulting in a functional shortening.

In approximately 15% of cases of hip involvement, other areas will also develop symptomatic osteonecrosis. These include knees, shoulders, wrists, feet, and, rarely, elbows and facial bones. Accordingly, these areas should be evaluated by history and physical examination. If there is any question of involvement, plain radiographs and perhaps a bone scan or an MRI should be obtained. Recently, MRI studies have indicated that the incidence might be considerably higher than expected. Take a careful history, looking for possible etiologic or associated factors. High doses of corticosteroids and prolonged, excessive alcohol intake are most often implicated, but a number of other factors should also be considered, as discussed earlier. The quantities of alcohol or steroid required to cause osteonecrosis have not been exactly determined, and it is clear that there is a tremendous variation in the sensitivity of patients to these agents. For example, it has been shown that patients on corticosteroids who develop Cushinoid features are much more likely to develop osteonecrosis than individuals taking the same dose of steroid who do not become Cushinoid (52).

LABORATORY TESTS

In most instances, routine laboratory tests are within normal limits. In selected cases, serological testing can be used to rule out or diagnose other possible causes of hip pain. Although these tests do not diagnose osteonecrosis per se, they may identify certain risk factors, thus helping to support the diagnosis. These include sickle cell disease, systemic lupus erythematosus, hyperuricemia, abnormal amounts of circulating lipids, and subtle coagulopathies.

Abnormalities in coagulation factors have recently been identified in more than 70% of patients with previously diagnosed “idiopathic” osteonecrosis (45,46). They have also been identified in a large number of patients with osteonecrosis in whom other inciting factors, such as alcohol or steroids, are present. It is thus felt that either alone or in combination with other agents, these coagulation abnormalities may predispose to or cause osteonecrosis.

These abnormalities cannot be detected on standard measurements of coagulation, such as prothrombin time, partial thromboplastin time, and bleeding time, which are usually within normal limits. A more complete coagulation profile is therefore required to identify these factors. Thrombophilia may be associated with decreased levels of protein C, protein S, and antithrombin III (AT III); increased resistance to activated protein C (RAP-C); and elevated antiphospholipid antibodies. Hypofibrinolysis may be associated with increased plasminogen activator inhibitor activity (PAI-1), increased lipoproteins, and decreased stimulated plasminogen activator activity. Unfortunately, at the present time these tests cannot be performed in all facilities, and they are expensive.

FUNCTIONAL EXPLORATION OF BONE

The earlier literature recommended that certain invasive tests, referred to as “functional exploration of bone,” be performed in patients suspected of having osteonecrosis despite normal radiographs (12,38,49,52). These included intraosseous venography, intraosseous pressure measurements, and histologic examination of core biopsy specimens taken from the femoral head. Although these tests can often lead to the diagnosis of osteonecrosis prior to the development of radiographic changes, they are seldom indicated if MRI is available. Rarely, histologic evaluation may be useful in distinguishing between osteonecrosis and certain other conditions affecting the femoral head, such as TOH (18,39,49,48,49).

IMAGING MODALITIES

Plain Radiographs

The most important modality for the diagnosis of osteonecrosis is high-quality anteroposterior (AP) and lateral radiographs of both hips. Initially, these will be within normal limits. The bony edema that takes a period of weeks to months after the initiating event for changes to appear on radiographs. The first changes to be noted are areas of radiolucency and sclerosis within the femoral head, usually in the anterior superior quadrant. These result from bone resorption and new bone formation. Infrequently, the earliest finding is diffuse osteopenia. If present, this must be differentiated from other conditions, including inflammatory arthritis, reflex sympathetic dystrophy, and TBSO. If small, and particularly if it is not in a region of major weight bearing, spontaneous healing may occur. Once radiographic changes are present, however, they rarely disappear completely, and the involved area can usually be identified by its sclerotic appearance.

Most untreated hips will not heal spontaneously but will show evidence of progression. Once established radiographically, the lesion will rarely enlarge in size, but microfractures through weakened, dead trabeculae will occasionally result in the presence of a crescent sign. This is seen in only a small percentage of hips with osteonecrosis and represents an area in which the supporting trabeculae have collapsed from beneath the subchondral bony endplate prior to flattening of the articular surface. Gross flattening of the femoral head later develops (Fig. 125.5), and, when this occurs, the crescent sign is usually obliterated. Fragmentation of bone in the necrotic region can often be identified. Usually the collapse progresses and the majority of the weight-bearing surface of the femoral head becomes flattened. Occasionally, the process seems to stabilize after only a small amount of flattening has occurred. In these instances, the joint line may be preserved for months to years, although secondary articular changes eventually develop. These are manifested by progressive joint-line narrowing, cystic and sclerotic changes within the acetabulum, and the development of marginal osteophytes. In longstanding cases, nearly complete obliteration of the joint line may eventually develop.

It must be emphasized that osteonecrosis is a disorder initially involving the subchondral bone of the femoral head. Joint-line narrowing and acetabular changes are secondary phenomena and usually develop only after femoral head collapse. An awareness of this fact will usually help in radiographically differentiating between osteonecrosis and a variety of arthritides, which, in the end stage, may look quite similar.

Magnetic Resonance Imaging

If osteonecrosis is suspected despite normal—or, appearing normal—plain radiographs, MRI of both hips should be obtained because more than 50% of cases are bilateral. If the diagnosis in one hip has already been established by plain radiographs, then MRI will add little to the evaluation of this hip, and the study may be performed on the contralateral hip only. However, the usual procedure is to obtain coronal sections of the pelvis, including both hips. The MRI picture of osteonecrosis is usually quite characteristic and, if both heads are involved, it may be pathognomonic (Fig. 125.7). The anterior superior quadrant of the head is usually affected, although changes may be seen involving nearly all of the head. Very rarely do these extend into the neck. If a significant amount of edema has developed adjacent to the necrotic lesion, this may occasionally lead to an abnormal MRI signal extending well into the femoral neck. In such cases, you must be cautious to differentiate osteonecrosis from TOH. The latter condition routinely involves both the femoral head and neck down to the intertrochanteric line and is manifested by a homogeneous, decreased signal intensity on the T1-weighted images and an increased intensity on the T2-weighted images, reflecting the presence of large amounts of edema fluid (Fig. 125.8 and Fig. 125.9). In osteonecrosis, the changes are usually confined to the superior portion of the femoral head, and the signal is most commonly decreased or irregular in both the T1- and the T2-weighted images. When present, the double-line sign on T2-weighted images is essentially pathognomonic for osteonecrosis (Fig. 125.7).
**Figure 125.7.** MRI images of a patient with bilateral osteonecrosis seen on plain radiographs. The T1-weighted image (top panel) shows subchondral lesions bilaterally composed of alternating areas of low and high signal intensity. The T2-weighted image (bottom panel) shows a high signal line inside the low signal on the right (double line sign). On the left, the lesion in the proximal portion of the femoral head has diffuse low signal intensity whereas the area below the necrotic lesion (asterisks) is isointense, indicating coexisting edema. (Courtesy of Dr. S. Hoffman, Danube Hospital of Vienna, Austria. From Bauer T, Plenk H. The Pathology of Early Osteonecrosis. Semin Arthroplasty 1998;3:192, with permission.)

**Figure 125.8.** Radiograph of a hip with transient osteoporosis. Note the marked osteopenia of the head and neck.

**Figure 125.9.** MRI of patient with transient osteoporosis or bone marrow edema syndrome of the right hip. Radiographs were normal. The right femoral head and neck show a diffuse low signal intensity in the T1-weighted image (top panel) and a high intensity in the T2-weighted image (bottom panel). (Courtesy of Dr. S. Hoffman, Danube Hospital of Vienna, Austria. From Bauer T, Plenk H. The Pathology of Early Osteonecrosis. Semin Arthroplasty 1998;3:192, with permission.)

**Other Imaging Modalities**

If high-quality AP and lateral radiographs are available, computed tomographic (CT) scans usually add little to the diagnosis of osteonecrosis. In selected instances, CT may better visualize a small lesion not easily seen on routine radiographs, and it may demonstrate small areas of articular surface collapse that are not apparent on plain films. It may also be used to help quantitate the extent of femoral head involvement.

Technetium bone scans have been used infrequently since the development of MRI. They are nonspecific and less sensitive than MRI and are only rarely positive if the MRI is normal. In such instances, other diagnoses should be considered. Bone scans may be of value when the MRI picture is atypical and further confirmation of the diagnosis is required, when a single screening test is desired to rule out the presence of multiple joint involvement, or when MRI is not available.

Limited studies have been reported with the use of single photon emission computerized tomography (SPECT), positron emission tomography (PET), and gadolinium-enhanced MRI. The roles of these studies in evaluating osteonecrosis have not yet been determined and they are currently not in routine use for this purpose (30, 44, 80, 97, 116, 118, 123, 131).

**CLASSIFICATION AND STAGING**

Once osteonecrosis has been diagnosed, the radiographic appearance of the hip is a good indicator of both the type and extent of the pathologic changes present. An effective method for classification and staging, based primarily on radiographs and other imaging modalities, serves many important roles. It helps establish a prognosis, follow improvement or progression of the condition, compare the effectiveness of different methods of treatment, and determine the best method of management for patients with different stages of osteonecrosis. Uniform use of such a system of classification should eliminate much of the current confusion about both the natural history and the treatment of osteonecrosis.

At this time, several different systems of staging are in use, some of which will be specifically described. In the 1960s, Arlet and Ficat in France (12) described a three-part staging system, and in the 1970s a fourth stage was added (39) (Table 125.3). This form is perhaps the one most widely used now, despite the fact that a stage 0 and a transitional stage were added later (38). Bone and marrow scans were mentioned but did not appear to be an integral part of the staging system, and MRI was not described. Certain invasive tests, such as intracapsular pressure measurements and femoral head biopsy, were deemed necessary to make the diagnosis in the earliest stages. Patients’ symptoms and physical findings were correlated with the stage. There was no attempt made to measure or quantitate the extent of involvement.
In 1973, Marcus et al. (74) identified six stages of osteonecrosis and described the radiographic picture for each. These were correlated with gross and histologic findings as well as with the patient’s symptoms and physical examination. Bone scans were not specifically described and MRI was not available at that time. No preradiographic stages were included and no attempt was made to quantitate the size of the lesion.

In 1974, Kerboul et al. (65) noted that the results of osteotomies performed for osteonecrosis depended on both the location and the extent of the lesion. This latter was expressed in degrees after measuring the arc of the articular surface involved as seen on both AP and lateral radiographs of the femoral head. Similar observations were reported by Wagner and Zeiler (139), Sugiyama et al. (128), and Koo and Kim (66).

In 1987, the Japanese Investigation Committee for Avascular Necrosis described a new roentgenographic classification (94,95). It focused on hips with Ficat and Arlet stages II and III, and it grouped them by the type and location of the lesion as well as the amount of articular surface involved. This system has not gained popularity outside of Japan. The Committee on Nomenclature and Staging of the Association Research Circulation Osseous (ARCO) in 1991 endorsed the staging system developed at the University of Pennsylvania in the early 1980s. In 1992, location of the lesion, as described in the Japanese system (10,42), was added, and in 1993, stages III and IV were combined, as were stages V and VI.

The University of Pennsylvania staging system identified seven distinct stages, incorporated both technetium scans and MRI, and included a measurement of lesion size in both early and late stages. Symptoms and physical findings were considered important in determining treatment but were not specifically included as part of the staging (Table 125.4) (Fig. 125.10, Fig. 125.11, Fig. 125.12, Fig. 125.13, Fig. 125.14, and Fig. 125.15). This system of staging was compared in clinical use to older, nonquantitative systems and was found more effective in following the progression or resolution of the condition, evaluating the results of treatment, and establishing a prognosis (117,118,122). It is now generally recognized that the size or extent of the necrotic lesion is an important indicator of prognosis and determinant of the management, and it should be included in staging. Use of this staging system in conjunction with a clinical evaluation as described has enabled us to develop an algorithm that has proven helpful in determining treatment for patients with osteonecrosis (Table 125.5). It outlines treatment in general categories only because there are a number of specific options to be considered in each category.

EARLY MANAGEMENT

In this section, early is meant to include hips with little or no evidence of femoral head collapse and minimal or no symptoms or physical findings. Considerable controversy exists regarding the early management of osteonecrosis. Several different procedures have been described, and in general most give results better than nonoperative or symptomatic treatment. It is, however, difficult to compare the effectiveness of each of these or to determine their specific indications and contraindications. This is because of the many variables included in these studies and the significant differences in techniques, inclusion criteria, radiographic evaluation, outcome measurements, and criteria for determining success or failure. A coordinated series of prospective studies is required to determine the effectiveness and indications for each of these techniques, but this is not yet available.

No method for treating early osteonecrosis of the femoral head is completely satisfactory. The natural history of this condition after clinical diagnosis is one of progression in most instances, except perhaps where lesions are small and in an area of relative non-weight-bearing. Thus, a procedure that retards this progression...
and provides an increased period of survivorship of the femoral head before arthroplasty is required should be considered at least partially successful.

**PREVENTION**

Even more important than the treatment of a disease state is its prevention. In osteonecrosis, certain specific risk factors have been identified and these should be eliminated or minimized to the extent possible. This applies particularly to alcohol ingestion and steroid administration, the two leading causes of osteonecrosis, as well as to smoking. In regard to steroid use, altered dosage schedules and the substitution of other agents have already led to a decrease in the incidence of osteonecrosis under these circumstances in which the use of corticosteroids has not yet been completely eliminated. Established guidelines for divers and those working under hyperbaric conditions must be followed. When they become generally available, medications shown to be effective in combating some of the known causes of osteonecrosis should be appropriately utilized in those patients particularly at risk.

**MEDICAL MANAGEMENT**

Certain systemic disorders have been associated with an increased incidence of osteonecrosis. These include coagulopathies, hyperlipidemias, and the presence of specific antibodies. Screen patients with osteonecrosis for the presence of these disorders, with coagulation studies, liver function tests, lipid profiles, and tests for anticardiolipin antibodies and lupus anticoagulant. If definite abnormalities are found, decide whether to treat them and which agents to use. Limited studies have shown a possible role for stanozol, an anabolic steroid that alters lipoproteins and suppresses clotting factors; nifedipine, a vasodilator; agents that lower circulating lipid levels, or radiation in the latter category to treat numbers that have been treated to date. Anticoagulation is not a benign form of treatment, and the appropriate dose and duration of treatment has not been established. In general, neither the effectiveness nor the safety of these agents has been determined, nor do we have appropriate guidelines for their use at present. We can hope they will prove to be effective and will be available for the prevention and treatment of osteonecrosis in the not too distant future (43).

**PROTECTED WEIGHT BEARING**

When a patient is diagnosed with osteonecrosis of a weight-bearing joint, there is a natural desire on the part of the treating physician to protect the involved area from excessive stress by using some form of limited weight bearing. Thus, canes or even crutches are frequently prescribed. Although these may decrease the degree of discomfort in patients who are symptomatic, they have not been shown to alter the natural course of this disorder.

Protected weight bearing may be used empirically as an alternative to surgical management in cases with a good prognosis. These cases include small, asymptomatic lesions and those in regions of relatively low weight bearing, such as the medial aspect of the femoral head. However, it has not been established that limited weight bearing improves the already favorable course in such instances. Symptomatic management, including protected weight bearing, may be the treatment of choice when the patient's age, general prognosis, and associated medical conditions, or the patient's own wishes, contraindicate surgical intervention.

Protected weight bearing is mandated following certain types of surgical procedures, such as core decompression, grafting, and osteotomies, where it is used as an adjunct to the therapeutic approach. However, some prefer to protect patients with osteonecrosis in the weakened regions from fracture, and perhaps protects the femoral head as well, until the healing processes have progressed satisfactorily. Perhaps the most important role for protected weight bearing is in the patient with relatively advanced stages of osteonecrosis, when it is felt that prophylactic procedures are of little avail. Here the use of a cane or perhaps crutches can diminish symptoms and improve function considerably until such time as a reconstructive procedure is indicated (81,85,94).

**ELECTRICAL STIMULATION**

Various types of electrical stimulation have demonstrated an ability to enhance bone formation and fracture healing. It was thus natural for electrical stimulation to be applied to patients with osteonecrosis, either alone or as an adjunct to other surgical procedures, in the hope that it would stimulate healing of the necrotic regions.

Three specific signals have been used: direct current (DC), capacitive coupling (CC), and pulsing electromagnetic fields (PEMF). The latter two are transmitted to the involved bone by means of surface electrodes or coils placed on the skin over the involved region. Thus they can be used alone or in conjunction with surgical procedures. DC stimulation requires the insertion of an electrode directly into the bony region to be stimulated, and therefore it has been used as an adjunct to core decompression rather than as an independent treatment modality.

Only limited studies have been reported using these techniques (13). Capacitive coupling, with the specific signal utilized, failed to show any enhancement of the effects of core decompression and bone grafting alone. DC stimulation, despite indications of an early response, did not show a long-term effect. Results with PEMFs, both in individual studies and in a multicenter study, were promising (14). They were shown to be more effective than symptomatic management in precollapsed and minimally collapsed hips; as effective as core decompression in precollapsed lesions; and more effective in hips with early collapse, both as determined by radiographic progression and delaying the need for arthroplasty. A special signal, different from that used to treat fractures, was used to treat osteonecrosis. At present, this is not generally available for routine use in the United States. If further evaluation by other investigators confirms these early positive findings, PEMF may be added to the treatment modalities available for this condition (1,4,119).

**CORE DECOMPRESSION**

During the early 1960s, Arlet and Ficat (12,38,39) used core decompression to examine the pathologic changes in femoral heads of patients who were suspected of having AVN. This procedure caused a decrease in the abnormally elevated intraosseous marrow pressures and frequently produced immediate relief of preoperative pain. Subsequently, this approach was used as a therapeutic rather than a diagnostic procedure. It is presumed to work by decreasing the abnormally high intraosseous pressures present in osteonecrotic lesions, by opening up channels for vascular ingrowth, and by stimulating the natural processes of repair.

This technique can be utilized as described or it can be supplemented with loosely fitted cancellous or cortical grafts, electrical stimulation, or various agents with the potential to stimulate bone healing, such as bone morphogenetic protein (BMP) and demineralized bone matrix (DBM) (21).

Investigators do not completely agree as to the safety or the effectiveness of this procedure. In 1985, Ficat and Arlet (39) reported on 133 hips in stages I and II treated with core decompression. They noted “good and very good results” in 90% of hips clinically and in 79% of hips radiographically. In 1986, Camp and Colewel (25) retrospectively reviewed 40 core decompressions performed by 13 surgeons in their area. Sixty percent of hips treated before collapse failed either radiographically or clinically, and all hips treated after collapse were considered clinical failures. Four patients sustained postoperative fractures.

Although opinion remains somewhat divided on the efficacy of core decompression, most studies report a low incidence of complications and results significantly better than with symptomatic management. In an extensive review of the literature published in 1996, Mont et al. (61) reviewed 42 reports of 2,025 hips, of which 1,206 were treated by core decompression and 819 by nonoperative means. Satisfactory results were found in 64% of hips treated by core decompression, compared with only 23% of hips treated nonoperatively. In the hips treated before collapse, good results were obtained in 71% with core decompression and 35% treated nonoperatively. The best results were achieved at centers doing the greatest number of procedures (37,81,85,110,124).

**Operative Technique**

We have modified the surgical technique somewhat from that originally described by Ficat, Arlet, and Hungerford (12,38,88). Our technique is as follows:

- Use a standard fracture table with a biaxial image intensifier in place.
- Expose the lateral femoral cortex through a short linear incision.
- Divide fascia and muscles in line with their fibers in routine fashion, and identify the flare of the greater trochanter.
- Place a small drill hole in the mid-lateral cortex at the point where the bone begins to flare laterally. Insert a small guide wire through this hole into the center of the lesion in the femoral head, using the image intensifier.
- Then open the lateral femoral cortex with a conical reamer or cannulated drill, to a diameter of 10 mm. Insert an 8 mm Michele trephine over the guide wire and manually advance to a depth of approximately 5 mm of the articular surface. Take care not to perforate the joint.
- Bone from the intertrochanteric region is considered essentially normal; put it aside to be used later for grafting. The necrotic segment can be identified because of the sclerotic bone encountered and the resistance to advancement of the trephine.
- Then place the trephine in the lesion, in stages, into the necrotic segment, removing bone from the trephine with an obturator as soon as significant resistance is met and further progression of the trephine ceases. Do not strike the instrument with a mallet. On occasion, it is difficult or impossible to remove all of the necrotic specimen from the proximal portion of the femoral head using the trephine. In such cases, remove the last few millimeters of bone with either a cannulated or a solid drill.
- Send abnormal bone for histologic examination.
- After the large central channel has been created, make two additional channels with a 5 or 6 mm Michele trephine. These extend from the initial opening in the cortex to other segments of the necrotic lesion. Accomplish this simply by slightly changing the angle of insertion of the trephine. Additional holes through the cortex are not required (Fig. 125.16 and Fig. 125.17).
Since 1981, more than 400 hips with osteonecrosis (University of Pennsylvania stages I–IV) were treated at the University of Pennsylvania with a modified core decompression using supplemental cancellous bone grafting. Results were determined by clinical evaluation, radiographic resolution or progression, and the need for THR. The results were compared to 55 hips treated nonoperatively prior to the start of this series and to results reported in the literature. Of 297 hips with a minimum 2-year follow-up, 64% did not require further surgery during the 2- to 14-year period of follow-up. This contrasted with only 23% of hips treated symptomatically. In the operative group, hips not requiring THR showed a mean improvement of 10 points on the Harris Hip Evaluation scale. A number of these hips showed a small degree of radiographic progression despite satisfactory clinical results; however, this was significantly less than in hips treated nonoperatively. Of hips in stages I and II undergoing decompression, 39% were radiographically stable, compared with only 19% of hips treated nonoperatively. THR was required in 31% of hips treated prior to femoral head collapse and in 49% of hips treated after collapse was apparent. There was a clear correlation between outcome and lesion size. In stages I and II, hips with small lesions involving less than 15% of the femoral head by volume required THR in only 22% of cases, compared with 40% of the hips with medium to large lesions involving more than 15% of the head. We noted no clear correlation with etiology except for patients in whom both corticosteroids and alcohol were implicated. These did slightly worse than other groups.

The complication rate was low. Five complications were recorded in 420 hips. Two patients sustained transcervical fractures after falling during the first month following surgery, one patient had a massive but nonfatal pulmonary embolism, one developed pneumonia, and one was diagnosed with proximal thromboembolitis of the thigh.

Our results corresponded closely with those reported from a review of the literature by Mont et al. (81,119). We concluded that compared to nonoperative or symptomatic management, core decompression with or without cancellous grafting was a safe and effective procedure for the treatment of AVN. At present, we recommend core decompression, with or without cancellous grafting, as a treatment for most hips with earlier stages of osteonecrosis, including those with a small to moderate degree of femoral head collapse but without acetabular involvement or significant pain or disability (stages I to IV-B) (Figs. 125.19). This procedure is used in both symptomatic and asymptomatic hips, as we found no correlation between symptoms and outcome in hips treated prior to femoral head collapse. Results in hips with very small lesions, especially those not in a region of major weight bearing, were considerably better than in the group as a whole, and the question has been raised as to how much the operative procedure adds to the outcome. Accordingly, these patients are now given the option of nonoperative management with close observation. Surgery is recommended, however, at the first sign of progression.
OSTEOTOMIES

Various types of osteotomies have been utilized in the treatment of osteonecrosis of the femoral head over the past 30 years (13,33,65,72,76,83,106,133). These are technically demanding procedures that are not frequently employed in North America. Results vary considerably, and subsequent arthroplasty may be compromised. The most commonly cited rationale for their efficacy is the biomechanical effect of moving the necrotic segment of the femoral head from the principal weight-bearing area of the hip to an area that bears less weight, and replacing it with relatively normal bone and cartilage. Others have suggested that the beneficial effects of osteotomies are secondary to the procedure effecting a reduction in venous hypertension and intramedullary pressure (13).

Two general types of osteotomies have been described: varus or valgus osteotomies, usually combined with flexion or extension, and trochanteric rotational osteotomies. The varus or valgus osteotomies have been associated with variable rates of success after short-term follow-up of approximately 5 years (13,72). Recent reports also include a prospective study of valgus-extension osteotomies combined with curettage and bone-grafting of the necrotic segment in a group of non-corticosteroid-associated hips (106). These authors reported a good or excellent clinical result in 36 of 45 hips (80%) at a mean follow-up of 65 months (range, 32 to 126 months). In a recent study of varus osteotomies combined with flexion or extension (85), there were 28 of 37 good and excellent outcomes (76%) at a mean follow-up of 11.5 years (range, 5 to 18 years). In patients without a corticosteroid association in this study, there were 17 of 20 successful clinical outcomes (85%).

The indications for varus or valgus osteotomies depend on the location and size of the lesion. Osteotomies may be utilized for both pre- and postcollapse lesions, but they should usually not be performed if there is acetabular involvement. Osteotomies work best when the lesions are small or medium sized with a combined necrotic angle of less than 200° (Fig. 125.20) (65) or with less than 30% of femoral head involvement. For varus osteotomies, there should be at least 20° of the superolateral femoral head not involved with disease, because this area of cartilage will be shifted into weight bearing after the osteotomy. Likewise, a valgus osteotomy requires normal bone and cartilage in the central or medial aspect of the head. Guidelines for when to add a flexion or extension component to the osteotomy are similarly based on the location of the lesion. Extension can be added when the necrotic segment is posterior and flexion can be added if the lesion is anterior.

Valgus Osteotomy with Flexion and Bone Grafting

Valgus osteotomy with flexion and bone grafting (106) is utilized in hips with Ficat Stage III when the osteonecrotic segment is confined to the anterosuperior part of the femoral head (less than 20% posterior involvement). Optimally, patients are less than 45 years of age and are not on steroids or chemotherapy.

- Expose the hip joint through an anterolateral approach, with an anterior capsulotomy permitting visualization of the femoral head.
- Insert guide wires to obtain the desired valgus and flexion.
- Cut the initial osteotomy perpendicular to the femoral shaft at the intertrochanteric level 1.5–2.0 cm inferior to the seating chisel.
- Make the bone wedge with a power saw and excise the anterior and lateral bone wedge.
- Use an AO right-angle or 95° blade-plate to fix the osteotomy.
- After fixation of the osteotomy, fenestrate the femoral neck anteriorly, just inferior to the head.
- Curet out the necrotic bone and elevate the collapsed subchondral area with a punch if necessary.
- Firmly pack cancellous bone graft from the iliac crest into the cavity created.

Postoperatively, allow patients toe-touch weight bearing (15 kg) for 3–4 months or until radiographs show healing of the osteotomy. Partial weight bearing may be continued for 6 months or longer, depending on the rate of healing of the femoral head.

Varus Osteotomy with Flexion or Extension

Varus osteotomy with flexion or extension (83) is utilized for small- or medium-sized lesions with a combined necrotic angle of less than 200°. There should be no radiographic evidence of acetabular involvement, and an arc of at least 20° on the lateral aspect of the femoral head should be free of underlying necrotic bone. The femoral head is moved into abduction and the femoral shaft is brought into adduction and flexion. This brings the necrotic area anteriorly, inferiorly, and medially.

- Place the patient supine on a radiolucent operating table with a small bump under the hip. Use a lateral approach to the proximal femur with the fascia lata and vastus lateralis split adjacent to the intermuscular septum. Expose the hip joint only if a flexion osteotomy is being performed. This is to facilitate an anterior capsulotomy to allow extension of the hip if necessary.
- Obtain the desired angular correction by two osteotomies that remove a triangular segment of bone. Determine the amount of varus correction desired by preoperative AP radiographs. Use lateral radiographs to determine flexion or extension components of the osteotomy.
- Perform the osteotomy with a power saw and hand-held osteotomes. Start the first cut on the lateral cortex at the vastus ridge. Use a fixed-angle AO blade plate or sliding hip screw to fix the osteotomy.

Postoperatively, keep the patient at toe-touch weight bearing for 2 months and then advance to a cane until union is visible on radiographs (Fig. 125.21), usually 4–6 months after the procedure.
Rotational Osteotomies:

The primary goal of osteotomy in the treatment of osteonecrosis is to shift the necrotic segment of bone out of the region of major weight bearing and to replace it with normal bone and cartilage. The effectiveness of conventional angulation osteotomies is necessarily quite limited by the amount one can alter the normal neck–shaft angle without impairing motion and function of the hip. However, this is not encountered when performing rotational osteotomies. The head can be rotated 90° or more around the head–neck axis without interfering with hip function. Thus, these osteotomies should be more effective in shifting normal bone and cartilage into the major weight-bearing region.

In 1967, Wagner described a double intertrochanteric osteotomy to accomplish this. However, by 1977 he concluded that the clinical results with this procedure were no better than with conventional angulation osteotomies and abandoned it (139). In 1973, Sugiioka (125,127) reported on a different type of transtrochanteric anterior rotation osteotomy. More than 500 of these procedures were performed since 1972, and Sugiioka's results, especially in hips treated before significant femoral head collapse, were quite good (120,129). Unfortunately, these results could not be consistently duplicated by other investigators (133,136,132). In some instances, this might be explained by deviation from the specific indications for the procedure, the complicated operative technique, or the postoperative regimen outlined by Sugiioka.

In most instances, osteonecrosis involves the anterosuperior aspect of the femoral head, leaving the posteroinferior portion relatively intact. By rotating the femoral head anteriorly, the necrotic segment is removed from the region of major weight bearing and replaced with relatively normal bone and cartilage. Occasionally, rotation posteriorly rather than anteriorly will more effectively accomplish this goal. Varus or valgus can be added to the rotation. The exact plane and alignment of the osteotomy can be determined from a careful measurement of preoperative radiographs. It is essential that the indications and contraindications be clearly understood and that the details of this difficult operative technique and postoperative care be closely adhered to. A critical point is the absolute necessity of maintaining the blood supply to the femoral head by preserving the vascular pedicle of the medial circumflex femoral vessels, which is located beneath the quadratus femoris.

Indications Rotation osteotomy is indicated for the treatment of early to intermediate stages of osteonecrosis of the femoral head in which the acetabular cartilage is relatively unaffected. There must be sufficient normal bone and cartilage in the femoral head so that after rotation the intact segment occupies at least 36% of the weight-bearing surface of the acetabulum. Contraindications include whole-head necrosis, significant degenerative changes in the femoral head or acetabulum, and poor general health.

Operative Technique Preoperatively, good-quality AP and lateral radiographs must be evaluated and measured to determine the plane of the osteotomy and to be certain that the basic goals of the procedure can be met. (This procedure is described in greater detail in references 126 and 129.)

- Make a modified Ollier's incision and expose the capsule of the hip joint through a lateral approach.
- Osteotomize the greater trochanter and reflect it proximally with the attached tendons of the gluteus medius and minimus and the piriformis.
- Expose the lesser trochanter carefully to allow safe transverse osteotomy of the lesser trochanter; the adipose tissue, which contains the vascular pedicles of medial circumflex femoral vessels, is close to the osteotomy site.
- Transect the piriformis tendon and the short external rotator muscle–tendon units attached to the intertrochanteric fossa, and widely expose the capsule anteriorly and posteriorly.
- Dissect the quadratus femoris muscle carefully and leave some of the deepest fibers of the muscle intact, to avoid vascular pedicle injury. No attempt should be made to expose or identify the vessels of the pedicle.
- Divide the obturator externus muscle sufficiently during dissection; otherwise, the inferior portion of the joint capsule cannot be adequately visualized for capsulotomy. Also, incomplete transection of the obturator externus muscle will produce compression of the vessel pedicle during anterior rotation.
- Place Kirschner wires (K-wires) in the cut surface of the greater trochanter from lateral to medial; insert the first K-wire 1 cm distal to the intertrochanteric crest and perpendicular to the long axis of the femoral neck in the AP view (coronal plane) and direct it toward the inferior aspect of the lesser trochanter at the posterior margin of the cut surface of the greater trochanter.
- Insert the second K-wire in the anterior margin so that a line drawn between the insertion points of the two wires is perpendicular to the femoral shaft axis (not the neck axis) in the lateral view (sagittal plane). The second wire is parallel to the first K-wire.
- Place the third K-wire distal and parallel to the second wire. Make the K-wires different lengths for easy identification on radiographs.
- To confirm the sites of the wires and of the planned osteotomy, take a true AP radiograph of the hip in the neutral position in all planes with the knee flexed to 90°. On this AP view, the first and second K-wires should be superimposed and at 90° to the neck axis. When the first and second K-wires are not superimposed on the radiograph, the second K-wire insertion should be corrected forward or backward in the proper length, judging from the distance between the second and third K-wire.
- After performing the circumferential capsulotomy using special forceps, subluxate the femoral head to see the extent of necrosis and to evaluate the remaining intact surface of the head for its weight-bearing capability.
- Blood flow in the femoral head can be evaluated using a laser Doppler speckled method during surgery.
- Using a reciprocating saw, make a transtrochanteric osteotomy at 90° to the long axis of the femoral neck. Use the inserted K-wires as a guide for the osteotomy. As described previously, when the lesion is extensive so that the varus position requires a greater angle of anteverision, incline 10° to 15° more vertically.
- Then make a second osteotomy at the superior edge of the lesser trochanter. The angle between the first and secondary osteotomies in the AP view should be greater than 90°. This will help the proximal fragment contact the distal fragment after rotation.
- Place a 3 mm Steinmann pin in the superolateral corner of the proximal fragment from posterior to anterior, and then insert a second pin (a 2 mm K-wire) parallel to the first pin in the distal fragment.
- Cut the psas tendon, the remaining fibers of the obturator externus, and the vastus lateralis and capsule, which cross between the fragment anteriorly.
- Using the proximal pin as a handle, rotate the femoral head anteriorly (Fig. 125.22 and Fig. 125.23). In the case of posterior rotation, place a Steinmann pin in the superolateral corner of the proximal fragment from anterior to posterior. The second pin serves as a reference point for measurement of the angle of rotation.

Figure 125.22. Schematic of the Sugiioka transtrochanteric rotational osteotomy of the femoral head. (Courtesy of Professor Y. Sugiioka.)
Avascular Necrosis of the Femoral Head.

Figure 125.24. Postoperatively, keep the patient non-weight-bearing with crutches for a variable period up to 1 year (precollapse disease, stage I or II, at a mean follow-up of 8 years (range, 2–19 years). Their surgical technique for decompression combined with tibial autografts and fibular autografts or allografts. They reported successful clinical outcomes in 18 of 20 hips (90%) that had healing. Initial results were favorable (bone had been removed. The rationale for this procedure was that this bone graft would lend structural support to the articular surface while the femoral head was collapsed; and in hips with less than 20%, 72% collapsed (Satisfactory clinical results were achieved in 82% of stage 2, 72% of stage 3, and 52% of stage 4 hips. The incidence of recollapse of the femoral head was 15% within 6 months postoperatively.

Postoperative Management Apply skin traction of 2 kg continuously for the first week and for an additional 2 weeks at night only. Begin hip ROM exercises after the first postoperative week. Patients can perform their own active assisted ROM exercises throughout the day using a pulley system attached to the overhead frame on the bed to achieve hip flexion. Flexion over 90° should be achieved by 3 weeks postoperatively, after which allow the patient up in a wheelchair and to begin ROM exercises in the Hubbard tank.

About 6–8 weeks postoperatively, begin ambulation in a water tank, with the water level at the nipple line. The timing of this progression depends on the inherent stability of the osteotomy line. Progression to partial weight bearing with crutches proceeds as indicated by healing, but do not begin full weight bearing before 6 months postoperatively.

Results Kaplan-Meier survivorship analysis of 295 hips with a follow-up of 3 to more than 20 years was performed. At 15 years following surgery, 80% of hips did not require additional operative intervention. The need for a second procedure was significantly greater in patients in whom less than 20% of intact femoral head was repositioned within the acetabulum and in those with advanced stages of femoral head collapse preoperatively. Seven percent of hips in stage 2, 21% in stage 3, and 24% in stage 4 required prosthetic replacement [Japanese Investigation Committee for Idiopathic Femoral Head Necrosis staging system (66)].

Satisfactory clinical results were achieved in 82% of stage 2, 72% of stage 3, and 52% of stage 4 hips. The incidence of recollapse of the femoral head was 15% within 3 years and 21% within 10 years of osteotomy. In hips with more than 36% of normal head within the acetabulum, only 7% collapsed; in hips with 21% to 35%, 35% collapsed; and in hips with less than 20%, 72% collapsed (125,126,127,128 and 129).

Grafting Procedures

Bone-grafting procedures can be divided into two general categories: nonvascularized (19,20,23,35,41,56,76,82,98,102,109,114,142) and vascularized (16,22,57,77,134,135,143). Most of these procedures are designed to provide some degree of structural support to prevent collapse of the articular cartilage surface. There are several different types of nonvascularized bone-grafting procedures, and they differ considerably. The graft may be introduced through the femoral head, the neck, or the intertrochanteric area. Either cancellous or cortical bone can be used, and this can be obtained from the patient's own iliac crest, proximal femur, tibia, or fibula, or from the bone bank.

There are also various techniques for performing vascularized bone grafting. The graft may be taken from the ilium, fibula, or greater trochanter. It may involve a muscle pedicle, which contains its own vascular supply, or a microvascular anastomosis can be performed using regional vessels. These procedures have been used both before and after femoral head collapse but work best for precollapse lesions. They should not be utilized when there are obvious degenerative changes in the acetabulum.

Structural Grafts

Structural bone grafting was first described by Phemister (98) for posttraumatic osteonecrosis. The technique was later modified by Bonfiglio and Bardenstein (20) and Boettcher et al. (19), who also used it to treat nonunions and nontraumatic osteonecrosis. In these cases, nonvascularized autogenous tibial, fibular, or iliac crest bone grafts were introduced through a core track, which extended from the lateral femoral cortex through the neck and into the head at an angle of 45° after the necrotic bone had been removed. The rationale for this procedure was that this bone graft would lend structural support to the articular surface while the femoral head was healing. Initial results were favorable (19,20), but longer-term follow-ups indicated lower success rates (35,109). Buckley et al. (23) described the results after core decompression combined with tibial autografts and fibular autografts or allografts. They reported successful clinical outcomes in 18 of 20 hips (90%) that had precollapse disease, stage I or II, at a mean follow-up of 8 years (range, 2–19 years). Their surgical technique for free nonvascularized bone graft follows.

- Perform a core decompression as previously described with a 9 mm cannulated drill bit.
- Drill the infarct up to the subchondral bone.
- Then prepare the graft with a rounded proximal end and tapered distally to be press-fit through the lateral femur up into the head. The graft utilized can be autogenous ipsilateral tibial corticocancellous strips or intact fibula. Alternatively, an alllogenic fibular graft can be used.
- Confirm the appropriate placement of the graft by fluoroscopic imaging with its rounded proximal end within the lesion just underneath the subchondral bone.

Postoperatively, keep the patient non-weight-bearing with crutches for a variable period up to 1 year (Fig. 125.24).
Cancellous and Cortical Grafting through the Neck or Head

A number of authors have used cancellous bone grafting through a window in the femoral neck. A procedure reported by Ganz and Buchler (41) combined this with an osteotomy, similar to that later described by Scher and Jakim (156). Japanese investigators described a technique whereby autogenous iliac crest strut grafts were inserted through a window into the neck and were impacted into position, thus elevating the collapsed femoral head to its former sphericity. The necrotic lesion was partially curetted and the strut grafts were supplemented with cancellous bone. They reported good or excellent results in 23 of 36 hips (61%), at a mean follow-up of 9 years (range, 2–15 years) (56,142). Rosenwasser et al. (132) replaced the necrotic bone with cancellous autograft and reported good to excellent clinical outcomes in 13 of 15 stages II and III hips followed for a mean of 12 years (range, 10–15 years).

In the so-called light bulb procedure of Rosenwasser et al. (102), the femoral head is approached through a window in the anterior aspect of the femoral neck. The necrotic material is excavated up to the subchondral bone. This cavity is then packed with autogenous cancellous bone harvested from the ilium. Postoperatively, patients remain non-weight-bearing for 6 months (Fig. 125.25).

Figure 125.25. Lightbulb procedure as described by Rosenwasser et al. (From Rosenwasser MP, Garino JP, Kiernan HA, Michelsen CB. Long-Term Follow-up of Thorough Debridement and Cancellous Bone Grafting of the Femoral Head for Avascular Necrosis. Clin Orthop 1994;306:17, with permission.)

Another method of introducing bone graft is through a trapdoor made in the articular cartilage of the femoral head. This was first described in detail by Meyers et al. (77,78), who utilized autogenous iliac cancellous bone grafting. Mont et al. (82) combined autogenous iliac cancellous and cortical bone grafting with demineralized bone matrix using this approach. They reported 22 of 30 good and excellent clinical outcomes at a mean follow-up of 4.7 years. Their trapdoor surgical procedure follows.

- Perform an arthrotomy using either an anterolateral or a posterolateral approach. Perform a capsulectomy and dislocate the hip.
- Using thin, sharp osteotomes, make a “trapdoor” in the articular surface over the collapsed segment by outlining three quarters of circle. Then hinge this osteochondral trapdoor back on the remaining one quarter of the osteochondral surface, revealing the sequestrum beneath.
- Use high-speed burrs and curets to remove all the necrotic bone until bleeding cancellous bone is encountered.
- Impact two to three iliac cortical struts into the base of the cavity.
- Surround the struts with cancellous bone to which demineralized bone matrix has been added.
- Replace the trapdoor and fix it with two to three absorbable pins.
- Relocate the hip and close the wound routinely. Keep patients at toe-touch weight bearing for 3 months and then advance to full weight bearing over the next 1–2 months (Fig. 125.26).

Figure 125.26. Trapdoor procedure as modified by Mont et al. (From Mont MA, Einhorn TA, Sponseller PD, Hungerford DS. The Trapdoor Procedure Using Autogenous Cortical and Cancellous Bone Grafts of Osteonecrosis of the Femoral Head. J Bone Joint Surg Br 1998;80:57, with permission.)

Osteochondral Grafts

There are only a few reports about the use of osteochondral allografts to replace the necrotic segment of the femoral head in the treatment of hips that have femoral head flattening combined with degenerative changes in the overlying cartilage (77,78). The hip is usually dislocated posteriorly, the depressed segment of articular cartilage and subchondral bone is removed, and the necrotic bone is then excavated down to a margin of viable bone. The cavity is first packed with autogenous, cancellous graft taken from the ilium. Osteochondral allograft is then placed over this, restoring the articular surface. Meyers and Convery (78) reported good and excellent clinical outcomes in 8 of 9 Ficat stage III hips with a mean follow-up of 3 years (range, 1–9 years). However, there are no long-term reports of this procedure. There are several technical difficulties inherent in this procedure. It can be extremely difficult to obtain a properly fitting osteochondral allograft in a timely fashion, because these grafts must be obtained from the donor within hours of the implantation and cannot be stored for prolonged periods. It is necessary to have an almost exact match in size between the donor femoral head and the head that is to receive the tissue. In addition, there are certain risks of infection as well as possible graft–donor mismatches that can lead to rejection.

Muscle-Pedicile Bone Grafts

As previously stated, there are multiple methods of utilizing muscle-pedicile bone grafts (16,57,73). The rationale for all of these procedures is that the muscle-pedicile bone graft will bring a blood supply to replace that lost by the necrotic tissue that is removed. This technique was first described by Meyers et al. (79), who used it in posttraumatic osteonecrosis. After the hip is exposed by a posterior approach, a capsulotomy is performed and the head–neck junction is identified. A segment of cortical bone with its attached quadratus femoris muscle is elevated and retracted. A longitudinal window is then made in the posterior aspect of the femoral neck. Through this window, necrotic bone from the femoral head is curetted out. The segment of cortical bone with its attached muscle is then placed into this channel, which extends through the neck and into the head. Cancellous bone is packed about this cortical graft as required. The cortical strut may be fixed in place using a single screw (Figs. 125.27).
Other investigators have reported the use of muscle pedicles using bone taken from the ilium. Most of the studies report satisfactory short-term results in 70% to 90% of precollapsed lesions at a mean follow-up of less than 5 years. It should be noted, however, that very few of these procedures have been reported to date, and these techniques are not in general use at this time. See Chapter 29 for a description of this technique as used for nonunion of the femoral neck.

Free Vascularized Fibular Grafting

During the past few years, there has been increasing interest in the role of free vascularized fibular grafting (FVFG) as a treatment for osteonecrosis of the femoral head. Only a few centers have significant experience with this technique, but they have reported encouraging results. This procedure is technically demanding, is ideally performed by two teams operating simultaneously, and requires assistance of a well-trained microvascular surgeon. Considerable experience is required before optimal results can be anticipated, and initially one should allow several hours for the procedure. The complication rate is significant, even in experienced hands, and stress fractures of the tibia have been reported. At the present time, it is difficult to determine if this procedure yields better results than simpler techniques, and if it does, how much better. The specific indications for it have yet to be established.

Indications We now perform this procedure in patients 20–40 years of age with symptomatic stage II to IV avascular necrosis of the femoral head. For patients younger than 20 years of age, the indications have been expanded to include stage V disease, given the limited treatment options in this age group. For those people 40–50 years of age, the indications have narrowed, so individuals with stage IV disease and greater than 50% femoral head involvement are not candidates for the procedure.

Ongoing corticosteroid use is not a contraindication for the procedure at our institution, but continued ethanol abuse and vascular compromise to the lower extremity are contraindications. At present we do not perform FVFG on asymptomatic patients, but we have found that a large proportion of individuals who are asymptomatic at initial presentation will progress to have symptoms within 5 years. This raises the question as to whether a prophylactic procedure should be performed even in patients with asymptomatic osteonecrosis, to help prevent progression. This issue continues to be debated.

Operative Procedure on the Hip Two surgical teams working concurrently shorten the duration of the procedure considerably. One surgeon operates on the lower leg while the other works on the hip. The average operating time at our institution is less than 3 hours.

Place the patient on the operating room table in the lateral decubitus position with the use of a bean bag. General anesthesia or spinal anesthesia is generally utilized.

Prepare and drape the entire lower extremity including the hip area. Make a curvilinear incision over the anterolateral aspect of the proximal femur (Fig. 125.28). Carry the incision down through the subcutaneous tissue, exposing the interval between the tensor fascia lata and the gluteus medius.

![Figure 125.28. Location of the tourniquet on the leg, and the location of the incisions for the approach to the hip and for harvesting the fibula.](image)

Split this interval and place a self-retaining retractor deep to the fascia.

The vastus lateralis can then be seen; reflect it distally to expose the lateral aspect of the femur. Pull the vastus lateralis distally and, with the use of a knife, cut transversely in the avascular plane of its origin on the vastus ridge.

Posteriorly, reflect approximately 5 cm of posterior lateralis off the linea aspera and sweep it distally using a periosteal elevator.

Anteriorly, detach the origin of the vastus intermedius carefully with a right-angle dissector and a knife, to create a trough that provides a shorter route for the ascending vessels and to eliminate tension on the vascular anastomosis (Fig. 125.29). Halt the dissection once the fat layer is encountered medial to the intermedius, to prevent injury to the vessels and the femoral nerve.

![Figure 125.29. Plane of dissection showing freed vastus lateralis (VL) swept distally, with a trough created in the vastus intermedius (VI). Ascending vein (V) and artery (A) are also shown. GM, gluteus medius; RF, rectus femoris; TFL, tensor fascia lata. (From Urbaniaik JR, Coogan P, Gunnneson E, Nunley J. Treatment of Osteonecrosis of the Femoral Head with Free Vascularized Fibular Grafting. A Long-Term Follow-Up Study of One Hundred and Three Hips. J Bone Joint Surg Am 1995;77:681, with permission.)](image)
The deep plane of dissection is between the rectus femoris and the vastus intermedius. Hold the plane open using the self-retaining retractor. The donor vessels for the anastomosis with the fibula are the ascending branches of the lateral femoral circumflex artery and vein. These ascending branches consist of a central artery and the other branches of the lateral femoral circumflex vessels are the transverse and descending.

For better visualization, release the aponeurotic bridge between the rectus femoris and the anterolateral femur. Expose the underlying fat and sweep it away with a sponge stick to reveal the ascending branches. These branches are consistently found 8–10 cm distal to the anterolateral iliac spine.

Then take down the vessels in a cephalad to caudal direction, starting at the first major division of the artery and veins. Clip the vessels with small vascular clips just distal to this bifurcation. This ensures adequate length of the vessels (about 4 cm), and the bifurcation affords a larger potential lumen size for anastomosis to help prevent vessel mismatch.

Dissect each vessel back to its origin, placing small hemostatic vessel clips on any small branches. It is technically easier to expose the vessels down individually rather than as a group.

Remove the non-weight-bearing ambulation for 6 weeks, followed by the coupler on the artery. A disposable suction mat of contrasting color is helpful in performing the microsurgery (KAM Super Sucker, Anspach, Palm Beach Gardens, FL), can also be utilized as bone graft. However, take care to avoid using the reamings from the necrotic area.

Approach the fibula via a lateral incision, simultaneously with the hip approach. Mark the line of the incision longitudinally in line with the fibula. Make the fibular bone cuts 15 cm apart, with the distal cut 10 cm proximal from the distal fibular tip. The incisional length should coincide with the level of the bone cuts (Fig. 125.30). The surgical details of fibular harvesting have been described elsewhere (Fig. 135) (see Chapter 36).

Final preparation of the fibula occurs on the back table. Immediately inject 40 ml of heparinized lactated Ringer’s solution into both veins and the artery of the pedicle to inspect for leaks. Reflect the pedicle from the proximal fibula until a large nutrient vessel is found entering the cortex. If the pedicle is not at least 5 cm long, dissect the bundle farther from the fibula so that the length of the fibular graft can be determined. The impactor has side windows at the area of the subchondral bone, and their position can be changed by rotating the impactor. Then place the bone obtained from the trochanter first, followed by the reamings.

Confirm the completeness of the grafting by placing renograffin in the canal and seeing obliteration of the necrotic cavity, using fluorescopy in the AP and frog-leg lateral projections.

Operative Procedure on the Fibula

Approach the fibula via a lateral incision, simultaneously with the hip approach. Mark the line of the incision longitudinally in line with the fibula. Make the fibular bone cuts 15 cm apart, with the distal cut 10 cm proximal from the distal fibular tip. The incisional length should coincide with the level of the bone cuts (Fig. 125.30). The surgical details of fibular harvesting have been described elsewhere (Fig. 135) (see Chapter 36).

Final preparation of the fibula occurs on the back table. Immediately inject 40 ml of heparinized lactated Ringer’s solution into both vessels and the artery of the pedicle to inspect for leaks. Reflect the pedicle from the proximal fibula until a large nutrient vessel is found entering the cortex. If the pedicle is not at least 5 cm long, dissect the bundle farther from the fibula. If the pedicle branches before 5 cm of pedicle can be mobilized, preserve both branches with subperiosteal dissection.

Then place the cancellous bone graft into the reamed cavity with the use of a custom-made impaction device. Use the scale on the surface of the device to measure the width of the bone tunnel so that the length of the fibular graft can be determined. The impactor has side windows at the area of the subchondral bone, and their position can be changed by rotating the impactor. Then place the bone obtained from the trochanter first, followed by the reamings.

Confirm the completeness of the grafting by placing renograffin in the canal and seeing obliteration of the necrotic cavity, using fluorescopy in the AP and frog-leg lateral projections.

Placement of the Fibular Graft into the Femoral Head

After complete removal of the contrast material from the core, insert the fibula with the pedicle located superiorly and anteriorly on the fibula. Position the pedicle into the fibular sulcus for better protection from the walls of the femoral tunnel. Placement of the fibular graft at the posterior border of the core allows the pedicle to be free from compression. The fit should be snug, but not tight, to ensure that the vessels are not being compromised.

Check the location of the fibular graft with fluorescopy. If the graft is not fully seated, it can be tamped into place.

Use a 0.062-inch wire to hold the graft in place; it crosses both cortices of the fibula and inserts into the medial cortex of the lesser trochanter. Take care to protect the pedicle during this step. Then cut the wire and bend it with a needle driver.

Remove the fluoroscopic unit. Place the hip retractor back into the hip wound with the four claw retractors attached to retract all four quadrants of the wound.

Bring in the microscope and place it in an optimal position for performing the vascular anastomoses.

Couple the vein first to diminish bleeding, which could obscure the field if the artery were anastomosed first. Use of a coupling device for the vein anastomosis decreases operative time. However, we prefer to anastomose the artery with interrupted 8-0 nylon sutures because of problems with intimal cracking upon placing the sutures.

Proceed with cannulated reamers over the guide pin, starting with a 10 mm reamer. The average female and male patients require final reamings of 16 mm and 19 mm, respectively, although this may vary depending on the size of the largest diameter of the donor fibula. The reaming extends to within 3–5 mm from the articular surface of the femoral head. It is safer to do the final part of the reaming using fluorescopy.

If the necrotic region involves greater than 25% of the femoral head, use a ball reamer to remove the remaining necrotic bone, which is depicted on fluorescopy as a cyst. The relationship of the remaining cyst to the bone tunnel can be better depicted by placing renograffin in the canal. Then use the ball reamer under fluorescopy guidance. Reintroduce renograffin into the tunnel to check that the necrotic bone is completely removed.

Then remove the cancellous bone from both the greater and the lesser trochanter with an upgoing and straight curet, respectively, through the bone tunnel opening. The cancellous bone reamings harvested from between the flutes of the reamers, both directly and by using a filtered suction tip (KAM Super Sucker, Anspach, Palm Beach Gardens, FL), can also be utilized as bone graft. However, take care to avoid using the reamings from the necrotic area.

Then place the cancellous bone graft into the reamed cavity with the use of a custom-made impaction device. Use the scale on the surface of the device to measure the width of the bone tunnel so that the length of the fibular graft can be determined. The impactor has side windows at the area of the subchondral bone, and their position can be changed by rotating the impactor. Then place the bone obtained from the trochanter first, followed by the reamings.

Confirm the completeness of the grafting by placing renograffin in the canal and seeing obliteration of the necrotic cavity, using fluorescopy in the AP and frog-leg lateral projections.

Postoperative Care

On the first day after surgery, get the patient out of bed and begin ROM exercises for the ankle and toes to prevent a flexion contracture of the great toe, which can result from dissection of the dissected flexor hallucis longus (FHL) muscle. Continue non-weight-bearing ambulation for 6 weeks, followed by progressive weight bearing. At 6 months, allow full weight bearing. If both sides are being treated in staged procedures, the second operation is done 3 months after the first.

Results

Successful outcomes with FVFG have been reported by many researchers. Yoo et al. (143) reported a 90% success rate at a follow-up interval of 3–10 years. Brunetti and Brunelli (22) achieved 78% good to excellent results with a follow-up of more than 5 years. Our initial 103 hips treated with FVFG were studied in detail, all with a minimum 5-year follow-up. We found a conversion to total hip arthroplasty (THA) in 11% of stage II hips, 23% of stage III hips, 43% of stage IV hips, and 32% of...
stage V hips that had undergone free vascularized bone grafting. Kaplan-Meier survivorship analyses of the initial 103 hips demonstrated that the probability of conversion to THA within 5 years after FVFG was 11% for stage II hips, 23% for stage III hips, 29% for stage IV hips, and 27% for stage V hips. No association was found between the etiology of the osteonecrosis and the likelihood of conversion to THA. The average postoperative Harris hip scores for those hips not converted to THA at 5 years follow-up were 80 for stage II hips, 85 for stage III hips, 76 for stage IV hips, and 75 for stage V hips (134).

Since this study, we have looked at our experience with 464 consecutive grafts with a follow-up of 1–17 years. The expected survival or time to conversion to THA of the vascularized fibular graft for all stages of osteonecrosis (including stage V) was more than 10 years (as determined by the Kaplan-Meier method of survivorship analysis). The overall survival in this series (all stages included) was 62.7%. There was, however, a greater failure rate for stage V osteonecrosis than for any other stage. Overall, excluding hips with stage V disease, the failure rate was 16.1% (93/579). The median time to failure, if it occurred, was 2.3 years. These relatively long-term results suggest that FVFG is a viable option for the treatment of advanced osteonecrosis of the femoral head (Fig. 125.31).

Figure 125.31. AP radiographs of a 46-year-old man with stage III osteonecrosis of the femoral head. A: Preoperative radiograph. B: Radiograph obtained 8 years postoperatively, showing preservation of the femoral head and joint space.

Complications The majority of complications with this procedure are related to donor site morbidity (22,134,143). In a study by Vail and Urbanik (137), the donor site morbidity from harvesting a free fibular graft was studied in 247 consecutive grafts in 198 patients. With a minimum 5-year follow-up, 24% of the lower legs were found to have donor site complications. These complications included a sensory deficit in 11.8% of the limbs, motor weakness in 2.7%, pain at the ankle in 11.5%, and pain in other sites in the leg in 8.9%. Two percent of the limbs had a contraction of the FHL. The FHL contracture was felt to be avoidable with careful stretching of the toes in extension during the first few postoperative days.

In 822 FVFG procedures of the hip performed at our institution, two patients had a deep vein thrombosis and one patient had a massive pulmonary embolus 6 weeks postoperatively. Generally, patients are maintained on one enteric-coated aspirin a day and persantine 50 mg three times a day for 6 weeks. Other complications included two superficial wound infections, one transient deep peroneal nerve paralysis, and one injury to a branch of the superficial peroneal nerve.

LATE MANAGEMENT

Late is defined as after significant femoral head collapse has occurred, with or without evidence of joint-line narrowing or acetabular involvement. It is usually associated with at least a moderate degree of pain and disability, although not infrequently patients with significant radiographic involvement (stages IV–V to VI) have relatively little discomfort. Under these circumstances, it is usually concluded that there is little chance of preserving the femoral head by the procedures previously described, and that some type of arthroplasty or hip reconstruction is virtually inevitable.

Most of the time it will be apparent whether the patients fits into the early or the late category. At times, however, the patient will fall somewhere between these two. In such cases, the experience and clinical judgment of the surgeon is paramount. The patient must be informed of his options and should enter into the decision as to whether to attempt to retard progression and postpone reconstructive surgery by some type of prophylactic surgery, or to accept the fact that reconstruction is inevitable and treat the hip symptomatically until arthroplasty is indicated.

PROTECTED WEIGHT BEARING

As mentioned earlier, protected weight bearing does not alter the natural progression of this condition. Thus, it should not be considered an alternative method of prophylactic management. In the late stages, however, it is a useful adjunct for symptomatic management of a patient who is not yet ready for a definitive arthroplasty. Intermittent use of a single cane or perhaps even two crutches at the discretion of the patient, together with a reasonable limitation of activities and the use of mild analgesics, will often decrease pain and enhance function.

CUP ARTHROPLASTY

Prior to the development of THR, cup arthroplasty was often considered the standard reconstructive procedure for patients with late stages of osteonecrosis, degenerative arthritis, and other arthritides. The postoperative regimen was lengthy and complicated, the results were inconsistent, and even relatively good results were generally not completely satisfactory by today's standards. Accordingly, conventional cup arthroplasty was essentially abandoned with the advent of THR.

Because osteonecrosis initially affects the femoral head and involves the acetabulum only much later, a number of surgeons have advocated performing arthroplasty on the femoral side alone, provided that the acetabulum is still relatively normal. This can be accomplished by using a modified cup arthroplasty or a femoral endoprosthetic replacement arthroplasty (25,53,67-93,108,116,132).

Investigators in France (65) modified the standard cup arthroplasty and referred to it as an adjusted cup arthroplasty. In this procedure, the femoral head is reamed and a snugly fitting metallic cup is impacted over it. The articular cartilage of the acetabulum is left intact. Kerboul et al. (65) reported on 80 hips treated by this operation and followed for 1–6 years. At follow-up, 66% were felt to be successful, 16% somewhat improved but still experiencing pain and a limp, and 16% failures. The failures were related to rotation of the cup on the femoral head, femoral head resorption and collapse, and acetabular erosion. The authors felt that with more rigid indications and improvements in techniques, the results could be improved.

Sedel et al. (108) reported satisfactory short-term results with the adjusted cup arthroplasty but later abandoned this procedure in favor of ceramic THR arthroplasty. In the United States, Nelson and Walz (63) modified the cup arthroplasty by cementing the cup onto the femoral head, leaving the relatively normal acetabular intact. They reported satisfactory intermediate-term results (17,65).

SURFACE REPLACEMENT ARTHROPLASTY

Surface replacement arthroplasty (SRA) was popularized in the 1970s as an alternative to conventional THR. It was thought to be especially suited for the young adult. Several different designs were available, and a number of procedures were performed in patients with osteonecrosis. Despite the theoretical advantages of this approach, the clinical results were unacceptable, with a high 5-year failure rate. The procedure was therefore virtually abandoned. However, McMinn et al. (75), Amstutz (5,5), and others have continued their work to eliminate the problems inherent in the original designs, which used thin polyethylene acetabular components cemented into place. Newer devices incorporate metal-on-metal articulations with acetabular components adapted for both cemented and cementless fixation. To date, results have been variable and we must await further reports with longer numbers and longer follow-ups to determine the roles that these components will eventually play in the treatment of patients with osteonecrosis (5,9,75,107,140).

HEMISURFACE REPLACEMENT

Hemisurface replacement, also known as cup hemiarthroplasty, is a direct descendant of cup arthroplasty, which was originally conceived by Smith-Petersen (111). Because it involves resurfacing the femoral head only, it is a viable treatment option for patients with osteonecrosis of the femoral head when bone quality is adequate and when acetabular cartilage is relatively normal. Because the femoral canal is not violated, nor is the femoral intramedullary diaphyseal bone compromised, as it is with THA, hemisurface replacement preserves bone stock, affording potential for easy revision. With normal transfer of stress to the proximal femur, proximal bone loss...
due to stress shielding may be mitigated. Cartilage durability is enhanced by optimizing contact of the hemispherical bearing to the acetabular cartilage. An added advantage of this technique is that the larger ball size ensures greater joint stability than with THA (7).

**Indications and Contraindications**

Hemisurface replacement is best performed in patients with adequate bone stock and relatively intact acetabular cartilage (Ficat stage III and early stage IV). It is especially suited for young and physically active patients as a way to postpone the need for THR (Fig. 125.32). Once collapse has occurred, we recommend that patients refrain from weight bearing from the point of identification onward, to minimize further damage to the acetabular cartilage. Patients with advanced osteonecrosis in which both sides of the joint are severely damaged are not candidates for hemisurface replacement, and full-surface or total hip replacement should be considered instead. In our practice, the underlying cause of osteonecrosis has not been a contraindication when considering patients for hemisurface replacement.

**Operative Technique**

Currently, we are using the CONSERVE (Wright Medical Technology, Arlington, TN) surgical system for hemisurface replacement. Available in millimeter increments from 42 to 54 mm for precision fitting, the CONSERVE prosthesis is made of cobalt chrome (Fig. 125.33). It has greater sphericity than other hemisurface designs to provide more coverage around the reamed bone, it has an expanded fixation area, and it employs a short stem to ensure accurate alignment with a uniform cement mantle around the resurfaced femoral head. These new design features enable us to deal with extensive bone stock abnormality or deformity, such as seen in Gaucher’s disease and perhaps sickle cell anemia.

A schematic diagram of femoral preparation for hemisurface replacement appears in Figure 125.34. A cylindrical reamer, an oscillating saw, and a chamfered cutter are used to remove necrotic areas and contour the femoral head. Instrumentation of the system is designed for nontrochanteric approaches, although the best surgical approach is the one with which the surgeon feels most comfortable. The anterior, modified lateral, and posterior approaches have been successfully performed.

Preoperatively, determine the approximate size and orientation of the prosthesis by using templates (Fig. 125.35), with final selection of prosthesis size made at the time of surgery. With adequate preoperative planning, there should never be a need to notch the neck.
We no longer use the transtrochanteric approach for surgical exposure, preferring the posterolateral approach, in which the circumference of the femoral head and neck can be assessed and the entire acetabulum can be completely visualized. This allows accurate assessment of the articular cartilage and optimizes our ability to precision-fit the prosthesis to the cartilage where it is best preserved, whether centrally or around the periphery. Section the gluteus maximus tendon at the point where it inserts into the linea aspera.

Next, divide the short rotators, the piriformis tendon, and the quadratus femoris. Tag the piriformis tendon for later repair.

To mobilize the femoral head, section the ligamentum teres with a ligamentum teres sectioner and complete the capsulotomy. The entire capsule must be removed to improve visualization of the articulating cartilage. We do not attempt to preserve the labrum.

Rotate the hip internally so that the femoral head can be inspected and so that pin placement down the central axis of the neck can be facilitated. Then use sizing ring gauges to estimate femoral head size, trying to obtain a snug fit at the widest part of the head.

Begin preparation of the femoral head. First, place the pin-centering guide firmly about the superior and inferior femoral neck, and insert a 3.2 mm Steinmann pin to a depth of approximately 10–20 mm.

Assess pin alignment in the femoral neck axis visually in two planes. Note that pin placement does not correspond to the center of the head; with the posterior approach, the pin-centering guide must be forced anteriorly to correct the tendency to retrovert the pin.

Then check correct positioning of the pin using the cylindrical reamer gauge by rotating it around the pin to confirm that there is equal clearance around the femoral neck. By using the cylindrical reamer gauge, proper pin placement can be achieved, and selecting a reamer that is smaller than the femoral neck should be prevented. Moreover, displacement of the cylindrical reamer from the neck axis, which could result in notching of the femoral neck during reaming, can also be prevented.

Initially, select an oversized cylindrical reamer (generally two sizes larger than the target size) to remove a small amount of bone. Attach this to the power source and advance it over the femoral head, using the Steinmann pin as a guide and taking care to clear debris and to stop reaming at the femoral head–neck juncture. Make successive reamings with appropriately smaller-size reamers until the final reamed head diameter is reached. Because each reamer has an intrinsic dome stop anthropomorphically designed to prevent notching, the cutting teeth will not penetrate the bone of the intertrochanteric area. These stops are effective when the largest cylindrical reamer used is no more than two sizes greater than the target reamer size (based on the templated neck dimensions of the conteralateral, normal neck, or measurement of the abnormal neck). However, as the reamer is advanced, regular visual inspection and finger palpation is advised to avoid neck invasion.

For the femoral dome resection, secure a cutoff guide, which corresponds to the size of the last cylindrical reamer used, onto the femoral head with one or two pins. Then resect the dome of the femoral head with a saber or oscillating saw.

Make the hole for the short neck stem of the component at this time by mounting the tower alignment guide assembly onto the cutoff guide.

Use a tapered stem reamer to ream distally to the sizing mark on the reamer corresponding to the target size of the component.

Then insert the chamfer guide into the central hole. Use the chamfer cutter that corresponds to the size of the final component to give the femoral head its final shape, significantly increasing the available fixation area.

Remove all remaining friable, yellow, nonviable necrotic bone with a curet or high-speed burr. We do not remove the dense reactive sclerotic bone.

Curet out any remaining cysts, and clean the bone with saline using pulsatile lavage. Then apply the translucent head protector.

Residual areas of poorly vascularized, sclerotic bone may be drilled using a 1.5 mm drill bit into more vascular bone to a depth of 3–5 mm.

Cut out any remaining cysts, and clean the bone with saline using pulsatile lavage. Then apply the translucent head protector.

Insert the acetalubar sizing gauge into the acetabulum and press it against the acetabular cartilage to visualize the contact areas. To optimize contact with the best remaining cartilage, perform several trials with larger or smaller acetalubar gauges. Then select a target component size, ensuring a preparation with a cement mantle of 1 mm. Generally, we recommend using the next larger size when the dimensions fall between millimeter increments, to provide peripheral or rim contact.

Before cement is applied, thoroughly clean both the reamed head and the acetabulum with pulsatile lavage to make certain all bone fragments and soft tissue have been removed.

Perform a trial reduction with the precision fit component. A radiograph at this point may be helpful to assess and verify correct component size. Check ROM before proceeding.

Mix the acrylic bone cement and pour it in a low-viscosity state into the component up to the circumferential recess. The timing of cement application onto the femoral head depends on bone density. If the bone is very compact and dense, cement should be applied in a less viscous state; if the bone is osteopenic, the cement should be applied when it has become more viscous to avoid deep penetration of the acrylic.

Where there is good bone quality, we prefer to avoid cementing the stem of the implant by inserting the chamfer guide temporarily into the dome hole for the stem during initial application; instead, we use finger pressurization of bone cement into the cancellous bone, especially the cylindrically reamed bone. Press the femoral component containing the doughy cement onto the prepared femoral surface and hold it rigidly until polymerization is complete.

Then reduce the hip and check it for ROM and stability.

Reattach the gluteus maximus and piriformis tendon and close the wound with one or more suction drains in place.

Begin ambulation on the first postoperative day, allowing weight bearing as tolerated. Have the patient use crutches for 4–6 weeks and a cane, if desired, for an additional 2–3 weeks. Permit sports at 4 months postoperatively. (See details of the surgical technique.)

Results

Our experience with hemisurface replacement began with a series of precision-fit titanium alloy shells (8,132) in 1980 and has gradually evolved into studies with ceramic and cobalt chrome shells (8,9). A total of 33 hips in 29 patients, with a mean age of 33.8 years at the time of surgery and an average follow-up of 5.1 years, were reviewed over our institution’s 20-year experience. Seventeen of the hips were classified as Ficat stage III and 13 as stage IV. Four have undergone revisions to either surface or total hip replacement. In the 29 remaining hips, the average UCLA hip scores are 8.1 for pain, 8.5 for walking, 7.5 for function, and 5.5 for activity.

Radiographic analysis showed no cases with loosening; in fact, one case even had bone fill in the acetabular fossa (8). To date, no dislocations have occurred with this group, due in large part to the stability provided by the larger ball size.

Although long-term results have largely depended on the quality of acetalubar cartilage, some are continuing to perform well at more than 15 years. Survivorship of this group is 81% at 5.1 years and 61% at 10 years (9). Revisions, when necessary, were all the result of acetalubar cartilage wear; however, some cases with rather advanced wear or bone loss at the time of surgery remain intact. Morbidity has been minimal, and no instances of sepsis, nerve palsy, thromboembolic events, or other complications have occurred. There have been no cases of prosthetic loosening, and bone stock has been well preserved and well maintained (8,9).

Retrieval studies of the titanium alloy implants have shown that although significant burnishing of the components occurred, the histologic response was benign (8). Some metallic debris and a few macrophages were found scattered throughout the tissue, located mostly in loose connective tissue. A change to cobalt chrome was precipitated by these findings, under the premise that a harder bearing-surface might extend the life of the cartilage and the durability of the prosthesis. Based on our own retrieval studies, we have established that the viability of the femoral head after hemisurfacings is preserved (8,51).
Whenever reoperation has been necessary, bone stock preservation and intact intramedullary canals have made revision to either full-surface or total hip replacement much like a primary replacement. No debris-induced granulomata were encountered. Because acetabular cartilage will undergo accelerated degenerative changes from articulating with metal, revision will eventually become necessary.

**Conclusions**

Based on our results and on a review of the literature, hemiresurfacing arthroplasty for Ficat stage III and early stage IV osteonecrosis is a reliable and successful time-buying procedure for young and active patients. Using this approach, only the diseased portion of the joint is surgically removed, and osteolysis and other complications such as dislocations are eliminated by avoiding the use of either bipolar or total hip replacement. Furthermore, the results of THA after hemisurface replacement are not compromised, and complete resurfacing can still be achieved.

Although we favor hemisurface replacement arthroplasty for patients with osteonecrosis who meet the indications outlined, there are many surgeons who prefer primary THR when an arthroplasty is required. A greater number of cases with a longer follow-up will be required to help determine which is the more successful approach.

**FEMORAL ENDOPROSTHETIC REPLACEMENT**

The rationale for using a femoral endoprosthesis rather than a THR for osteonecrosis once again stems from the fact that initial changes are in the femoral head and not the acetabulum. It was thus felt by some investigators that replacing only the femoral head would be more conservative than THR (25,116). The early procedures used solid press-fit femoral components that employed neither cement nor bone ingrowth for fixation of the stem into the femoral canal. The heads were sized rather crudely to the acetabulum because the importance of an exact fit was not realized at that time. The long-term results with these prostheses when used in younger patients with osteonecrosis were generally poor (Fig. 125.37), although some good to excellent results did occur (Fig. 125.38).

![Figure 125.37.](image)

**Figure 125.37.** Radiograph of the right hip of a patient with avascular necrosis treated with the insertion of an Austin Moore noncemented femoral endoprosthesis 12 years earlier. The femoral component remains well fixed within the shaft, whereas the ball has eroded superiorly and medially into the acetabulum. The patient required revision to a total hip arthroplasty.

![Figure 125.38.](image)

**Figure 125.38.** Fourteen-year follow-up of a cemented unipolar endoprosthesis. The patient has little pain and excellent function.

More recently, endoprostheses have been rigidly fixed into the femoral canal either by cement or by biological ingrowth. Modular components came into use and both unipolar and bipolar devices were employed. Initially it was felt that the use of a bipolar component would yield better results than a unipolar in that there would be less frictional wear on the acetabulum and thus a lower incidence of acetabular failure. Unfortunately, other problems with the bipolar prostheses developed, and there is currently little evidence of the superiority of the bipolar over the unipolar device (Fig. 125.39).

![Figure 125.39.](image)

**Figure 125.39.** Radiograph of the right hip of a patient who underwent a cemented bipolar endoprosthetic replacement 5 years earlier. Note the loosening of the femoral component in addition to the medial erosion of the acetabular component into the pelvis.

Although a number of surgeons continue to use femoral endoprostheses in patients with osteonecrosis, the current trend is away from these devices and toward THR arthroplasty or other procedures.

When the results of endoprosthetic replacement, using current techniques and components, are compared to THR, most reports indicate better results with THR. Because the stem design and the fixation of endoprostheses and total hips are now similar, it is probable that the difference in results can be attributed to problems within the acetabulum. A metallic femoral head places abnormal stress on the acetabular cartilage and creates a situation that is far from physiologic. This is not consistently well tolerated, even by normal articular cartilage, and it has been noted that the acetabular cartilage in osteonecrosis is no longer normal by the time arthroplasty is needed (24,25,31,67,136).

**TOTAL HIP REPLACEMENT**
Although THR is by far the most commonly used procedure for the treatment of patients with advanced stages of arthritis and other disorders of the hips, there has been a certain reluctance to advise this procedure for patients with AVN. This is because these patients are much younger than patients with degenerative joint disease at the time that arthroplasty is required, and it is generally accepted that the survivorship for THR in young patients is less than in older patients. In addition, patients with osteonecrosis seem to have a higher complication rate and earlier incidence of failure than patients of a similar age but with other disorders of the hip (98). In five reports published between 1981 and 1984 on THR arthroplasty in younger patients, the mean incidence of revision was 13%, and results were rated as good to excellent in 61% with a 5-year follow-up (3). Salvati and Cornell (105) reviewed their experience with THR in patients with osteonecrosis from 1972 through 1975. They found that 11 of 28 arthroplasties failed at a mean of 8 years (range, 5–10 years), for an overall failure rate of 37%. Of the remaining 18 THRs, 16 had good to excellent ratings. It was their opinion that the failure rate in osteonecrosis was four times greater than in osteoarthritis.

More recent literature, however, indicates improved results at short- and medium-term follow-up times with more modern components and techniques (21, 25, 40, 43, 54, 62, 71, 92, 99). In 1994, Piston et al. (100) reported on 35 hips with AVN treated with porous-coated THR arthroplasty. Follow-up ranged from 5 to 10 years with a mean of 7.5 years. They encountered one femoral and two acetabular revisions, for an overall revision rate of 6%. There was, however, significant remodeling in six hips and osteolytic reactions in six others. In 1997, Garino and Steinberg (53) reported on 123 THAs in patients with osteonecrosis. The follow-up was 2–10 years with a mean of 4.6 years. All femoral stems and 71 sockets were fixed with acrylic cement. Fifty-two sockets were designed for bone ingrowth. The average Harris hip score improved from 45 points preoperatively to 92 points at the time of last follow-up. Of the 246 components used, 8 acetabular and 4 femoral prostheses (4%) were revised. The incidence of revision for aseptic loosening was 2.5%. None of the noncemented acetabular components were either radiographically loose or revised. Fifty-two hips had a minimum follow-up of 5 years (mean, 6.6 years). In this group, five components (5%) were revised and four (4%) were radiographically loose. The revision rate for hybrid hips with a minimum 5-year follow-up was 2%. These results seem significantly better than reports of older series. The authors concluded that using modern techniques and components in THR arthroplasty can give excellent results over a period of 2–10 years, even in young patients with osteonecrosis. They felt that this procedure was the treatment of choice when reconstructive surgery was required (Fig. 125.40) and (Fig. 125.41).

**Figure 125.40.** Radiograph of the left hip of a husky young man with alcohol-related avascular necrosis, treated 11 years earlier with a cemented total hip replacement arthroplasty. The patient continues to do well clinically with minimal radiographic changes since the time of surgery.

**Figure 125.41.** A 19-year follow-up of a Müller total hip replacement in a young man with alcohol-related osteonecrosis. The prosthesis continues to function well.

### RESECTION ARTHROPLASTY

Resection arthroplasty, also referred to as a Girdlestone pseudarthrosis, was used as a primary arthroplasty for both septic and nonseptic hips prior to the advent of THR. It is used most frequently as a salvage for the failed and usually infected THR or endoprosthesis. Under certain selected circumstances, however, it can be used as a primary arthroplasty. In the patient with end-stage osteonecrosis whose pain and disability require some type of operative intervention, but in whom prosthetic replacement or THR is contraindicated, the resection arthroplasty may be a reasonable alternative. This procedure may be considered to treat the osteonecrotic hip complicated by sepsis, and the patient in whom THR arthroplasty has a high potential for complications and failure. Patients with chronic recurrent septicemia, those on renal dialysis, and individuals with active sickle cell disease may fit into this category. Resection arthroplasty might also be considered in the individual who is felt to be too unreliable to take proper precautions following THR, such as the chronic alcoholic, drug abuser, and mentally retarded. It also might be used for the individual who is confined to a bed/chair existence due to neurologic or medical problems and who simply needs pain relief and satisfactory motion rather than stability and the ability to ambulate.

Resection arthroplasty must be considered a compromise. If this is clear from the outset to both the patient and physician, and if there is an understanding of the advantages and disadvantages of this procedure, then most patients will be satisfied with the outcome. A resection arthroplasty will eliminate sepsis if present, provide pain relief, give a good ROM, and not deteriorate with the passage of time. At the same time, the joint will be unstable, the limb will be an average of 1–1.5 inches short, and most patients will require both a shoe lift and the use of at least one cane or possibly two crutches for ambulation (Fig. 125.42) (27, 121). Resection arthroplasty may be used as a definitive procedure or as an intermediate step, such as in the case of infection, until a THR can be safely performed.

**Figure 125.42.** Radiographs of the left hip of a 22-year-old man who developed a septic nonunion with avascular necrosis following open reduction and internal fixation of a displaced femoral neck fracture. **A:** Radiographs show the nonunion and loosening of the fixation device within the femoral head. **B:** Radiographs taken 3 years after a resection arthroplasty (Girdlestone pseudarthrosis). The patient is doing well clinically and has declined total hip replacement arthroplasty.
ARTHRODESIS

In the patient with significant pain and disability, who is no longer responsive to conservative management, and in whom prosthetic replacement or THR is contraindicated but stability of the hip rather than motion is required, arthrodesis rather than resection arthroplasty might be considered. Most of the indications described for resection arthroplasty also apply to hip fusion. This procedure might also be considered in the large, young, active man who desires a single “permanent” procedure rather than a THR with the need for more than a single revision during his lifetime. Before embarking on this procedure, the individual must be fully aware of the possibility that the attempt at fusion may not be successful, and of the permanent limitations that a fusion will impose. At times the use of a pantaloon spica as a trial will help the patient make an informed decision. The usual contraindications for hip fusion apply here as well and include pathology in the knees, lumbar spine, or contralateral hip. Because of the known high incidence of bilaterality of osteonecrosis, it is essential that involvement of the opposite hip be ruled out prior to embarking on a fusion. If, despite these precautions, osteonecrosis does develop in the contralateral hip, THR can be performed with a satisfactory outcome. The incidence of nonunion in osteonecrosis is somewhat higher than in patients with other disorders because of the necrotic bone present in the femoral head.

OTHER SITES AND TYPES OF INVOLVEMENT

THE KNEE: DISTAL FEMUR AND PROXIMAL TIBIA

Osteonecrosis can involve both distal femoral condyles or the proximal tibia (85,89,91). This is probably the second most common site of involvement after the femoral head, with one report (91) finding an incidence of knee involvement in 9% of patients with osteonecrosis. Two entirely separate entities can affect this region: One is known as spontaneous osteonecrosis of the knee (or SPONK), and the other, which will be referred to as avascular necrosis, is the disorder that can also affect the hip and other areas of the skeleton (Fig. 125.43). SPONK occurs in patients over 55 years of age, and it typically involves one femoral condyle or tibial plateau without other joint involvement. The risk factors commonly found in osteonecrosis of the hip have not been identified. AVN of the knee, on the other hand, is typically found in patients younger than 45 years of age, may involve several sites about the knee itself, is associated with hip involvement 90% of the time, has a different appearance on radiographs and MRI, and is often associated with corticosteroid use or alcohol intake.

Figure 125.43. Avascular necrosis of the knee with involvement of both femoral condyles and the tibial plateau. A: AP radiograph. B: MRI in sagittal projection.

Spontaneous Osteonecrosis of the Knee

In the SPONK disorder, patients have a sudden onset of pain, usually about the medial aspect of the knee. Radiographs are within normal limits initially, but the bone scan or MRI shows abnormalities involving the medial aspect of the knee more often than the lateral, with the femoral condyle being more frequently affected than the tibial plateau. The prognosis is based on the size of the lesion. When the involvement is greater than 50% of the transverse diameter of the condyle, the prognosis is worse than when the lesion is smaller. Initially, patients should be treated symptomatically with protected weight bearing. The condition often resolves over the course of the next several months. It is important to separate this entity from other conditions such as meniscal tears, so that unnecessary arthroscopic surgery is avoided.

Patients with larger lesions have a poorer prognosis and often go on to collapse despite protected weight bearing. A small number of cases have been treated with osteotomies, but the results have generally been unsuccessful, and larger lesions often lead to either hemiarthroplasty or total knee replacement. The results have been generally favorable. There is little experience with core decompression in these cases and there is no evidence that it affects the prognosis (191).

Avascular Necrosis of the Knee

Small lesions of the knee are usually treated nonoperatively with restricted weight bearing and analgesics. Larger lesions are more often symptomatic and have occasionally been treated by core decompression with moderate success. A recent study revealed satisfactory outcomes in 61 of 77 cases (79%), at a mean follow-up of 7 years (range, 2–16 years) (91).

There have been only a few reports of arthroscopic debridement or bone grafting for lesions about the knee (88). The results of total knee replacement in this group of patients have been disappointing. A recent report of 31 primary total knee arthroplasties followed for 8 years (range, 2–16 years) revealed only 17 good to excellent results (55%). These poor results may be related to the fact that the procedure was performed in young patients with high activity levels and with bone that was metabolically and structurally compromised (89).

THE HUMERAL HEAD

Involvement of the humeral head has been reported in 5% to 12% of patients with osteonecrosis (29,69,86). Involvement is bilateral in 50% of the patients when associated with corticosteroids. The initial treatment of this entity is symptomatic and includes gentle exercises to preserve strength and ROM and the avoidance of excessive stresses on the joint. There have been relatively few reports of core decompression; however, the best results have been obtained when the procedure was performed prior to humeral head collapse (88). A recent study (69) reported good to excellent results in 47 of 62 shoulders (76%) with a mean follow-up of 8.5 years (range, 2–18 years). Some shoulders may continue to function reasonably well even after humeral head collapse has occurred. In some, however, the pain and disability is sufficient to warrant either hemiarthroplasty or total shoulder replacement. These are described in only a few reports, and there is mixed opinion as to which of the two procedures should be utilized, even if radiographs do not demonstrate changes in the glenoid (63).

THE FOOT AND ANKLE

Although osteonecrosis of the talus is most often seen following fracture, atraumatic osteonecrosis is occasionally seen in association with involvement of the hip and other regions (34,86,90,136). Talar involvement is seen in approximately 2% of patients with osteonecrosis. Eighty percent of the patients are women and the disorder is noted bilaterally 50% of the time (Fig. 125.44). Other bones of the foot and ankle are also involved occasionally. These include the distal tibia, calcaneus, medial cuneiform, metatarsal heads, and distal fibula (Fig. 125.45). Treatment options include analgesics, bracing, or casting. Core decompression of the talus has been performed in a small number of cases. A recent report (86) noted satisfactory results in 29 of 32 cases. If these measures fail and the talus goes on to collapse, significant pain and disability may result, requiring tibiotalar arthrodesis or possibly pantalar arthrodesis (89). Fusion can be difficult to obtain. In one report (66), there were 8 of 9 nonunions (89%) following the first attempt. In another report (136), 9 of 11 ankles (82%) eventually went on to fusion, but multiple procedures were often required; these included autogenous bone grafting, crossed cancellous screws, tibial struts, the insertion of a blade plate, and prolonged casting.
THE ELBOW

Osteonecrosis of the adult elbow is encountered infrequently (70). One recent report (68) described eight adult patients with atraumatic osteonecrosis of the elbow. These included four men and four women with a mean age of 35. Four patients had an associated autoimmune disease, all had involvement of other joints, and all were on corticosteroid therapy. Four cases involved the capitellum, three the trochlea, and three the lateral condyle. Four elbows presented in the precollapsed stage radiographically and responded well to nonoperative management. Two patients with collapse failed nonoperative treatment and underwent core decompression for pain relief. One elbow with advanced disease required a total elbow arthroplasty. In contrast to the pediatric form of osteonecrosis, Panner’s disease, osteonecrosis of the adult elbow can lead to endstage arthritis.

MISCELLANEOUS CONDITIONS

Osteonecroses involving various bones in children and adolescents were previously grouped together with a variety of skeletal disorders collectively known as the osteochondroses. These include Perthes disease, Freiberg’s disease, Koöhler’s disease, and Kienboöck’s disease. With the exception of Perthes disease, these conditions are rarely encountered (120).

Perthes Disease

Perthes disease, or Legg-Calvé-Perthes disease, is the pediatric form of osteonecrosis involving the capital femoral epiphysis. It is usually found in patients between 4 and 10 years of age, affects boys 80% of the time, and is unilateral in 70% to 80% of patients. Pathologically, the disease is quite similar to the adult form, with dead bone and marrow always present. Subchondral fractures are common. As in the adult, evidence of repair occurs from granulation tissue that grows into the area of necrosis with new bone deposition upon dead trabeculae. The repair process is more successful in the pediatric patient than in the adult, with complete repair occurring often. The prognosis depends both on the age of onset and on the extent of epiphyseal involvement. Patients younger than 6 years generally have a good prognosis, as do patients in whom less than 50% of the femoral head is involved.

Freiberg’s Disease

Osteonecrosis of the metatarsal head, usually the second, is known as Freiberg’s disease or Freiberg’s infarction. This condition affects adolescent girls in 75% of cases. It has been postulated to occur after trauma to an elongated and more rigidly fixed second metatarsal. Treatment consists of a short-leg walking cast for 4 weeks, followed by metatarsal supports. The condition is usually self-limited and the prognosis is good. Occasionally patients do not have symptomatic relief and require operative treatment consisting of curettage and bone grafting, metatarsal osteotomy, or resection of the metatarsal head.

Koöhler’s Disease

Osteonecrosis of the tarsal navicular is known as Koöhler’s disease. It usually affects boys under 10 years of age, with one third occurring bilaterally. The cause of this disorder is unknown but it may be secondary to repetitive shear forces applied to the ankle joint. It may also be related to late ossification of this important weight-bearing bone. It is usually treated with arch supports and heel wedges unless severe symptoms warrant the application of a short-leg cast. The prognosis is excellent and the navicular becomes fully ossified in most cases.

Kienboöck’s Disease

Osteonecrosis of the lunate, or Kienboöck’s disease, usually affects the dominant wrist of young adults. It has been related to repeated trauma as well as to a genetic predisposition to a shortened ulna. In the early stages, treatment options include immobilization and symptomatic management. Radial shortening or ulnar lengthening have also been employed with some success. For more advanced stages with collapse of the lunate, surgical procedures include excision of the lunate, replacement with a synthetic implant or biological tissue, and wrist fusion.

Preiser’s Disease

Atraumatic osteonecrosis of the scaphoid is an uncommon condition that may be related to steroid administration or repetitive minor trauma, or it may be idiopathic. It often remains asymptomatic for quite some time before presenting as wrist pain and limitation of motion. Sclerosis and cyst formation often give way to fragmentation and eventually degenerative arthritis of the wrist. Treatment is similar to that for Kienboöck’s disease.

Osteonecrosis of the Capitate

Osteonecrosis of the capitate is a rare condition of uncertain etiology, although corticosteroids and minor repetitive trauma have been implicated. The clinical course, radiographic picture, and treatment are similar to those described for osteonecrosis of the lunate and scaphoid.

AUTHORS’ PERSPECTIVE

This chapter has focused on nontraumatic osteonecrosis of the adult hip because this is the region most frequently affected. Although the incidence of osteonecrosis is much lower than that of other disorders affecting the hip joint, it can no longer be considered a rare condition. Despite an increased interest over the past several years,
there is much yet to be learned about its etiology and pathogenesis. As with many conditions, prevention is perhaps more important than cure. We must therefore be aware of factors that contribute to the development of osteonecrosis and eliminate or minimize them to the extent possible. Recent studies have indicated that subtle coagulopathies are often involved, and this information may lead to more effective methods of treatment and prevention.

Although the prognosis for a hip with a small nécrotic lesion may be relatively good, especially if the area of involvement is not in a region of major weight bearing, most clinically diagnosed cases will progress to femoral head collapse without specific treatment. The majority of these will eventually require some type of arthroplasty. Symptomatic treatment, including protected weight bearing, is generally not successful. Our goal is therefore to institute some type of definitive treatment as early as possible. This, in turn, requires early diagnosis, which is now possible due to a heightened awareness of osteonecrosis in the medical community and to newer diagnostic modalities, particularly MRI.

Among the operative procedures available for the treatment of early cases of osteonecrosis are core decompression, various types of osteotomies, and several different grafting procedures. These have been described in some detail in this chapter. Unfortunately, it is difficult to compare accurately the results of these procedures and to determine their relative indications because of the many variables that exist in reports published to date.

Once significant collapse of the femoral head has occurred, prophylactic measures are far less effective. At this stage, patients are generally treated symptomatically until pain and disability necessitate some type of arthroplasty. Although THR is currently the procedure most often selected, other choices include femoral endoprosthetic replacement and modified cup arthroplasty or hemisurface replacement, if the acetalabulum is relatively uninvolved. It has yet to be determined whether it is best to perform this type of limited procedure to buy time before THR is required, or to proceed directly with THR.

If the acetalabulum has undergone secondary degenerative changes, THR is usually the procedure of choice. This is a reliable operation that yields excellent pain relief and function. The major concern is with long-term survivorship, because most patients with osteonecrosis are young. However, recent studies indicate improved durability with newer techniques and devices.

Our future goals include learning more about the etiology and pathogenesis of this condition so as to prevent its occurrence when possible. Research must continue on medical approaches to prophylaxis and treatment. Methods for early diagnosis will continue to improve, and the medical community at large must be made even more aware of the importance of early diagnosis and early treatment. The search should continue for better techniques to treat early cases of osteonecrosis.

Controlled, prospective studies should be instituted to evaluate and compare the various procedures available so as to determine the relative effectiveness and the specific indications for each. These must include uniform inclusion criteria and effective methods of evaluation and staging.

For hips with femoral head collapse but without significant acetalabular involvement, we should continue to evaluate and develop better types of limited arthroplasties.

For hips in the later stages, where acetalabular changes are already well established, we must improve the durability of THR arthroplasty. With advances in surgical technique and in component design, materials, and manufacturing, it is quite possible that the useful life of a THR arthroplasty will be extended considerably so that these components may last a lifetime, not only in the older patient, but also in the younger patient with osteonecrosis. When this occurs, there will be a dramatic improvement in our ability to handle patients with even the most advanced stages of this frustrating condition.

HISTORY OF LIMB SALVAGE SURGERY

Limb salvage surgery is defined simply as removal of a neoplasm that otherwise would be treated by amputation. Limb salvage usually requires two separate but equally important procedures: (a) “adequate” removal of the tumor and (b) bone and soft-tissue reconstruction. Although the technique of limb preservation for bone tumors has only recently been popularized, isolated reports of various forms of limb salvage were published 40 years ago. At that time, low-grade tumors such as giant cell tumor and chondrosarcoma were treated by removal of the bone followed by osseous reconstruction. Usually the only options were autogenous arthrodesis and allografts. Resection arthrodesis of the knee was one of the earlier techniques described. The femoral “turn-down” or tibial “turn-up” arthrodesis was a procedure used to fuse the knee after resection of tumors involving the lower end of the femur or the upper tibia. When successful, this procedure led to knee fusion, but it was also associated with a significant complication rate.

During the 1960s, several reports on the use of human bone allografts were published. Three separate centers for this surgical procedure developed, with Ottolenghi working in Argentina (99,100), Parrish in the United States (104), and Volkov in the Soviet Union (138). These surgeons reported variable outcomes with the use of allografts for limb salvage following tumor resection. Approximately one third of their patients had an excellent outcome, one third failed, and the remaining third had reasonable results. The enthusiasm for the use of allografts increased after several reports by Mankin et al. from Boston (82,83,87and 88), who showed that allografts could be used successfully and recommended that the mechanical and biological issues be studied.

During the late 1970s and the 1980s, limb salvage surgery became a very popular technique. This was the result of several advances. First, the imaging of bone and soft-tissue tumors improved dramatically. With the use of computed tomography (CT) scans, radionuclide scans, and magnetic resonance imaging (MRI), these tumors could be visualized precisely, and this allowed for adequate removal (26). Second, Enneking (34) carefully studied the natural history of mesenchymal tumors so that surgeons could better understand how these tumors progress and the natural barriers to their progression. In addition, Enneking et al. (40) further defined surgical margins by developing staging systems for both benign and malignant tumors. These staging systems and margin definitions are still used today.

Also during the 1970s and 1980s, there were developments in chemotherapy for bone malignancies, including osteosarcoma, malignant fibrous histiocytoma, and Ewing’s sarcoma (69,113). At that time, several drugs that are effective in treating these tumors were identified and their use was well defined. Necadjuvant chemotherapy was developed—the delivery of cytotoxic drugs prior to removal of the tumor, which leads to tumor necrosis and better oncologic outcomes. When used prior to limb salvage surgery for osteosarcoma, such drugs have been shown not only to improve patient survival, but also to reduce the risk of local recurrence to a level comparable to that for amputation (89). Simon et al. (123) compared survival data for limb salvage surgery to that for amputation and found comparable results. This further increased the enthusiasm for limb-preserving techniques, particularly because surgeons realized that patient survival would not be jeopardized.

The final technological advancement that improved the results of limb salvage surgery was the development of better reconstructive options. Allograft techniques improved during the 1980s and 1990s, and modular prosthetic replacements were developed. In addition, a combination of implants and allografts were tried with success. All of this has led to limb salvage surgery with better functional outcome and fewer complications.

NATURAL HISTORY OF BONE TUMORS

Much of our knowledge of the natural history of orthopaedic neoplasms can be attributed to Enneking (34) and his colleagues. They studied many whole-mount surgical specimens and thereby were able to determine the natural progression of bone tumors, which led to improved surgical procedures with better oncologic outcomes.

High-grade sarcomas progress in a centripetal fashion. Bone sarcomas start either within the medullary space or toward the surface of the bone. Surface tumors can be either periosteal or parosteal, originating from either the periosteum or the surface of the bone. As malignant tumors progress, they do not respect natural barriers. They have a tendency to destroy the medullary cancellous bone. In addition, bone sarcomas can extend up the medullary space involving marrow and can be associated with “skip” lesions (37). Skip lesions are defined as discontinuous extensions of tumor within the medullary space of the bone with a disease-free interval. As the tumor progresses within the medullary space, the cortex is ultimately destroyed, frequently leading to soft tissue extension. Nearly 90% of osteosarcomas have both bone and soft-tissue extension at the time of presentation (Fig. 126.1). The host is unable to marginate a bone sarcoma, and an inflammatory and vascular zone—typically an infiltrative margin and a pseudocapsule—develops in the margin between the normal tissue and tumor. The pseudocapsule is a zone that is contaminated by microscopic islands of tumor, and therefore it does not represent a true barrier.

During the late 1970s and the 1980s, limb salvage surgery became a very popular technique. This was the result of several advances. First, the imaging of bone and soft-tissue tumors improved dramatically. With the use of computed tomography (CT) scans, radionuclide scans, and magnetic resonance imaging (MRI), these tumors could be visualized precisely, and this allowed for adequate removal (26). Second, Enneking (34) carefully studied the natural history of mesenchymal tumors so that surgeons could better understand how these tumors progress and the natural barriers to their progression. In addition, Enneking et al. (40) further defined surgical margins by developing staging systems for both benign and malignant tumors. These staging systems and margin definitions are still used today.

Also during the 1970s and 1980s, there were developments in chemotherapy for bone malignancies, including osteosarcoma, malignant fibrous histiocytoma, and Ewing’s sarcoma (69,113). At that time, several drugs that are effective in treating these tumors were identified and their use was well defined. Necadjuvant chemotherapy was developed—the delivery of cytotoxic drugs prior to removal of the tumor, which leads to tumor necrosis and better oncologic outcomes. When used prior to limb salvage surgery for osteosarcoma, such drugs have been shown not only to improve patient survival, but also to reduce the risk of local recurrence to a level comparable to that for amputation (89). Simon et al. (123) compared survival data for limb salvage surgery to that for amputation and found comparable results. This further increased the enthusiasm for limb-preserving techniques, particularly because surgeons realized that patient survival would not be jeopardized.

The final technological advancement that improved the results of limb salvage surgery was the development of better reconstructive options. Allograft techniques improved during the 1980s and 1990s, and modular prosthetic replacements were developed. In addition, a combination of implants and allografts were tried with success. All of this has led to limb salvage surgery with better functional outcome and fewer complications.

NATURAL HISTORY OF BONE TUMORS

Much of our knowledge of the natural history of orthopaedic neoplasms can be attributed to Enneking (34) and his colleagues. They studied many whole-mount surgical specimens and thereby were able to determine the natural progression of bone tumors, which led to improved surgical procedures with better oncologic outcomes. High-grade sarcomas progress in a centripetal fashion. Bone sarcomas start either within the medullary space or toward the surface of the bone. Surface tumors can be either periosteal or parosteal, originating from either the periosteum or the surface of the bone. As malignant tumors progress, they do not respect natural barriers. They have a tendency to destroy the medullary cancellous bone. In addition, bone sarcomas can extend up the medullary space involving marrow and can be associated with “skip” lesions (37). Skip lesions are defined as discontinuous extensions of tumor within the medullary space of the bone with a disease-free interval. As the tumor progresses within the medullary space, the cortex is ultimately destroyed, frequently leading to soft tissue extension. Nearly 90% of osteosarcomas have both bone and soft-tissue extension at the time of presentation (Fig. 126.1). The host is unable to marginate a bone sarcoma, and an inflammatory and vascular zone—typically an infiltrative margin and a pseudocapsule—develops in the margin between the normal tissue and tumor. The pseudocapsule is a zone that is contaminated by microscopic islands of tumor, and therefore it does not represent a true barrier.
Early on, sarcomas such as osteosarcoma that involve the distal femur will respect cartilaginous barriers such as the growth plate or articular cartilage. Later, however, penetration through these structures occurs (125). Rarely, osteosarcoma will even enter the knee joint at cruciate ligament attachments.

Note that during the process of bone destruction, there is significant weakening of the bone, which may lead to a pathologic fracture. The exact mechanisms of osteolysis are not fully known. The process may be the result of proteolytic enzymes or a prominent osteoclastic response. During the process of tumor progression, the tumor outgrows its blood supply and spontaneous necrosis occurs. This necrosis reflects aggressive tumor biology and should not be misinterpreted as a chemotherapeutic response.

Finally, bone sarcomas can metastasize. As many as 80% of osteosarcomas have either microchmetastatic or macrochmetastatic disease at the time of presentation, as Link et al. (72) demonstrated in a clinical review. Rarely will a bone sarcoma metastasize to regional lymph nodes. The bone itself is another potential metastatic site, and it should be screened by radioisotope image scans. This understanding of the natural progression of bone sarcomas is useful conceptually when discussing surgical margins, because in surgical resection the interface between the tumor and the host is so important. Also, the effect of adjuvant therapy such as radiation, chemotherapy, or both on tumor progression has a significant impact when determining the appropriate surgical procedures.

SURGICAL MARGINS AND STAGING

Enneking et al. (40) can also be credited with our current definition of surgical margins. Four types of margins have been described. The first is intralesional: The surgical dissection enters the tumor, leaving gross residual tumor within the bed. This type of margin is inadequate for bone sarcomas unless effective adjuvants are used to eradicate the residual tumor. There have been some isolated reports combining intralesional excision of bone sarcomas with adjuvants such as liquid nitrogen. These procedures should be considered experimental and reserved only for low-grade bone sarcomas.

The second margin is described as a "marginal" margin: removal of the tumor en bloc, but with the plane of dissection passing through the reactive zone surrounding the tumor (Fig. 126.2). This margin conceivably will leave microscopic disease in the tumor bed and by itself is not adequate for most bone sarcomas. When combined with adjuvants, however, it may be an adequate margin that is associated with a relatively low local recurrence rate. Some authors have shown this to be the case with effective neoadjuvant chemotherapy for osteosarcoma. For example, Picci et al. (107) have shown that effective chemotherapy marginates an osteosarcoma; at least conceptually, the reactive zone around the tumor becomes a true capsular margin. For the most part, oncologic surgeons try to obtain more than a marginal margin when removing bone sarcomas.

Finally, there is the radical margin: en bloc removal of the tumor along with the bone from joint to joint and muscle from origin to insertion. This type of margin completely removes not only the tumor but also the reactive zone surrounding the tumor. It is considered the gold standard for most bone sarcomas and should be effective unless there is a skip lesion.

In summary, most bone sarcomas are removed by wide en bloc resection. Margins, however, are getting "closer" as a result of better tumor imaging as well as effective neoadjuvant chemotherapy, which creates a barrier around the tumor. With the use of CT and MRI, it is possible to evaluate the tumor more precisely. The surgeon can then plan the resection preoperatively and decrease the need for removal of extensive amounts of normal tissue. With less normal tissue resected, functional outcomes are improving without the sacrifice of acceptable oncologic results.

The most common staging system for bone sarcoma is known as the Enneking system (40), which consists of three stages. Stage I includes low-grade bone sarcomas. Examples of stage I tumors are parosteal osteosarcoma, low-grade medullary osteosarcoma, and low-grade chondrosarcoma. Stage II tumors are
TUMORS OF THE DISTAL FEMUR

The distal femur and proximal tibia are common sites for both benign and malignant tumors. As an example, in the Schajowicz series of osteosarcoma published in 1994 (114), 347 out of 621 (56%) of osteosarcomas occurred in the lower end of the femur or the upper end of the tibia. The distal femur was the more common site, accounting for 229 patients. Malignant fibrous histiocytoma also commonly occurs about the knee. In the Huvos series (53), the femur accounted for 32% of the malignant fibrous histiocytomas. With a potential malignancy about the knee, it is necessary to perform appropriate staging biopsy.

The lesion is usually imaged with anteroposterior and lateral radiographs. This gives the first clue as to the type of neoplastic process occurring. A typical “conventional” osteosarcoma is a medullary tumor that involves the metaphysis or epiphysis, or both, of the lower end of the femur or upper end of the tibia. This tumor is characterized by bone destruction and frequently is associated with soft-tissue extension (Figs. 126.4, 126.5). Variable amounts of ossification are seen in osteosarcoma except for the telangiectatic variant. Radiologic features such as “sunburst” or Codman’s triangle, which is bone formation as a result of periosteal elevation, can be seen on plain radiographs.

The next step in the imaging workup includes a technetium-99 diphosphonate bone scan and three-dimensional imaging. The technetium-99 diphosphonate bone scan is typically “hot” in osteosarcoma and will pick up multicentric disease (63). The three-dimensional imaging can be either a CT scan or an MRI (7,8,25,116). An MRI is particularly useful in determining the soft-tissue extension of the tumor and its relationship to the neurovascular bundle. This is important for tumors about the knee where posterior extension toward the neurovascular bundle is common. Usually, a pushing-type margin occurs that is readily seen with an MRI. An MRI is also useful in determining the intramedullary extent of the tumor; in addition, it picks up skip lesions. It can also determine the presence of transphyseal extension of the tumor and joint penetration, both of which are important when planning limb salvage surgery. Rarely is angiography necessary. Perform chest radiographs and a CT scan of the chest to determine the presence of metastatic disease to the lungs (19).

Once the imaging has been completed, perform a biopsy. Biopsies of the lower end of the femur or upper end of the tibia need to be performed carefully because their execution will critically affect ultimate limb salvage surgery (12,33,84,122,124). The biopsy can be either by needle or open. Needle biopsy with a skinny needle provides limited histology, and diagnosis is made primarily by cytologic features. Only an experienced pathologist can make an accurate diagnosis from a skinny needle core biopsy. Needle biopsy, on the other hand, enables more tissue for histologic analysis (67,68,95,114,115). The most dependable procedure for diagnosis, however, is open biopsy, which provides adequate amounts of tissue for extensive pathologic examinations and makes it possible to perform a frozen section to confirm that diagnosable tissue has been obtained.

Placement of the biopsy is important. The biopsy incision or needle puncture must be placed in an anatomic location that can be totally excised at the time of definitive limb salvage. Incisions must be longitudinal, and it is preferable to enter the tumor by passing through muscle rather than anatomic planes. It is best to biopsy the soft-tissue component of the tumor. Perform immunohistochemistry on all suspected round cell tumors as well as potential metastases. The biopsy is an important step during the sequence of events leading to limb salvage and is not without its hazards, as Mankin et al. reported (86). They found that inappropriate biopsies can lead to a false diagnosis or complications such as hematomas and bone fractures, and might possibly preclude the possibility of limb salvage. Therefore, this procedure needs to be carefully planned, preferably by the tumor surgeon contemplating limb salvage, so that no opportunities are lost.

TUMORS OF THE DISTAL FEMUR

Once patient evaluation, staging, and biopsy have been completed, many patients are placed on neoadjuvant chemotherapy, particularly those with osteosarcoma and Ewing's sarcoma. This delivery of cytotoxic drugs for a period of time prior to resection of a tumor facilitates limb salvage by tumor shrinkage, tumor margination, and tumor necrosis. Some tumors, such as chondrosarcoma, are not sensitive to chemotherapy, and currently surgical resection represents the only means of eradicating them.

Tumors of the distal femur can be resected by either an intra-articular or an extra-articular procedure. The latter is reserved for those tumors where there is evidence of joint contamination. This contamination can be demonstrated by MRI or by joint aspiration and cytologic examination of fluid. With extra-articular resection, the quadriceps mechanism is disrupted, significantly limiting reconstructive options. The most reliable reconstruction after extra-articular resection of the distal femur is knee arthrodesis.

Fortunately, most tumors of the distal femur are amenable to intra-articular resection, which can be performed through either an anteromedial or an anterolateral extensile approach (Fig. 126.5). We prefer to use a long anteromedial longitudinal approach with a tibial tubercle osteotomy, using a sterile tourniquet after gentle gravity exsanguination.
On the skin, draw out a long anteromedial longitudinal approach, elipsing out the prior biopsy site. Take this site en bloc with the tumor.

On reaching the deep fascia, perform a medial parapatellar arthrotomy along with a tibial tubercle osteotomy to evert the patellar mechanism and displace it laterally.

Perform the tibial tubercle osteotomy with a power-oscillating saw, taking a block of bone approximately 3 cm in length and 1 cm in depth, which includes the tubercle. Some predrill the fragment for replacement and fixation with a screw. This leaves an ample cancellous bed for reattachment at the end of the operative procedure.

After everting the patellar mechanism, flex the knee and inspect the joint. Determine of the amount of resection of the quadriceps based on soft-tissue tumor extension.

Take a cuff of normal tissue encircling the soft-tissue component of the tumor to achieve wide margins. This usually requires taking the vastus intermedius muscle along with a portion of either the medialis or the lateralis, depending on the anatomic location of the tumor. Preserve the remaining quadriceps mechanism by careful dissection.

At this point, flex the knee acutely and perform the intra-articular dissection. Divide the anterior cruciate ligament close to the tibia, and divide the medial collateral ligament and posterior medial joint capsule.

Divide the iliotibial band laterally by Gerdy’s tubercle, and also divide the lateral collateral ligament at the joint line. Similarly, release the posterolateral capsule.

Divide the medial and lateral heads of the gastrocnemius muscle along with the posterior cruciate ligament and then finally the posterior capsule, which allows the knee to be readily subluxed anteriorly.

The next part of the dissection is to identify the femoral artery and vein in Hunter’s canal, and dissect them carefully away from the tumor. There are numerous perforating vessels that need to be ligated to allow the vascular bundle to fall away from the posterior distal femur.

Sharply divide the attachments to the linea aspera.

Cut the femoral shaft with a power-oscillating saw.

An MRI coronal image is frequently used and measured to determine the resection length. Select a clear margin beyond the tumor based on the MRI and divide the bone. Cut the remaining soft-tissue attachments and remove the distal femur. We prefer at least a 3 cm margin beyond the tumor.

It is desirable to bisect the specimen either in an isolated area of the operating room or in the pathology lab to check for gross margins. If the margins are adequate, then perform the reconstruction with new gowns, gloves, and instruments.

If an extra-articular resection of the distal femur is necessary because of joint contamination, the procedure is different (Fig. 126.6). A tibial tubercle osteotomy is not performed, and the joint is not opened during the operative procedure.
INDICATIONS AND CONTRAINDICATIONS FOR LIMB SALVAGE ABOUT THE KNEE

In recent years, there has been increased enthusiasm for limb salvage for tumors about the knee. As previously mentioned, Simon et al. (123) have demonstrated that limb salvage can have oncologic outcomes similar to those for amputation, as, for example, in their study reviewing osteosarcoma. There are, however, relative contraindications for limb salvage. Tumors involving the knee are frequently associated with a soft-tissue mass. If the mass involves the neurovascular bundle, then limb salvage should be reconsidered, particularly if the nerve is involved. The vascular bundle can be resected with the tumor and later reconstructed, but resection of the knee joint and sciatic nerve is a relative contraindication to limb salvage. Extensive skin involvement is also undesirable for limb salvage. Yet another relative contraindication is the presence of large bulky sarcomas that do not respond to chemotherapy. Joint contamination by sarcoma can be considered for limb salvage, but it usually requires extra-articular resection of the knee. Reconstruction is an important issue when determining the feasibility of limb salvage. The lifestyle or vocational demands of some patients are also relative contraindications for limb salvage. Consider durability of the reconstruction when deciding the advisability of limb salvage.

Finally, skeletal maturity is a critical feature. Sixty percent of limb growth occurs at the distal femoral and proximal tibial physes. Resection of these growth plates in very young children will lead to significant inequality of limb length. Generally patients under the age of 10 are not good candidates for limb salvage. Special techniques that allow for skeletal growth, such as an expandable prosthesis, are still experimental.

A surgical technique that has been well described for young children is the rotationplasty (13,65,89). This is not a form of limb salvage because the foot is used as a knee joint and the patient is fitted with a prosthesis. This procedure, however, leads to better function than conventional above-the-knee amputation. In 1966, Winkelmann (145) described the indications for rotationplasty. He included children under 10 years of age for whom wide margins with limb salvage were not possible. For this procedure, the sciatic nerve needs to be intact in the thigh. Winkelmann reported on 121 rotationplasties of various types; from this group there was only one local recurrence. He felt the oncologic results were similar to amputation, and the functional results exceeded conventional amputation. Complications included loss of limb circulation in seven patients, development of nonunion in four patients, and malrotation in five.

A promising technique for skeletally immature patients with tumors involving the distal femur or upper tibia is the option of intercalary resection with joint preservation. More specifically, tumors involving the metaphysis of the distal femur with an open growth plate can potentially be treated by a transphyseal resection, preserving the articular surface with intercalary reconstruction. It is critical to determine whether the tumor crosses the physis, which would be a contraindication for this type of limb salvage. This type of resection can also be done for tumors involving the upper end of the tibia.

RECONSTRUCTION OF THE KNEE AFTER RESECTION

There are two options for knee reconstruction after resection of the upper end of the tibia and lower end of the femur: arthrodesis and arthroplasty. Each procedure has advantages and disadvantages, and these need to be carefully discussed with the patient prior to making a management decision.

Arthrodesis

A successful arthrodesis is a durable, stable limb. Because there are no moving parts, the physical restrictions are fewer. Manual labor is possible after knee fusion, and impact-sports activities are also possible, especially if the arthrodesis is obtained with living bone. However, late fractures have been reported for arthrodesis achieved by intercalary allograft. The disadvantages of a knee fusion are the technical difficulty in achieving a solid fusion and the loss of knee motion. The latter makes ambulating on uneven terrain difficult. It is also difficult to rise from a sitting position, and activities that require stooping are impossible. Knee arthrodesis may also cause problems with the ipsilateral hip and spine. Despite these limitations, patients can be quite functional and even participate in some sports.

There are several ways to achieve knee arthrodesis. One way is to use an intercalary allograft (Fig. 126.9). After the tumor has been resected, a properly screened frozen bone allograft can be placed in the osseous defect. Generally, the same type of bone that is removed is selected, and the articular cartilage is removed from the allograft so that the cut surface of the allograft coapt with the cut surface of the upper tibia (28,142). This creates a large cancellous bone surface for fusion to occur. It is important to fix the allograft rigidly at both ends (Fig. 126.10). This is accomplished either by a long intramedullary rod from the greater trochanter to the ankle, supplemented with a compression plate to prevent rotation, or by an osteosynthesis with two dynamic compression plates. This graft can be supplemented with a vascularized fibular bone graft to aid in healing.

Figure 126.9. Intercalary allograft arthrodesis.
Another technique is the use of a dual fibula autograft to fuse the knee after resection of the lower femur or upper tibia (Fig. 126.11). The problem with these grafts is that they are prone to stress fracture and usually need to be supplemented with autogenous iliac graft. They do not present the same broad cancellous surface for arthrodesis that an allograft affords. When a vascularized fibular autograft is used, hypertrophy of the fibula has reportedly occurred, especially with stress fractures of these grafts. Enneking and Shirley (39) described the use of local bone grafts along with an intramedullary rod to fuse the knee. The anterior cortex of the tibia is removed and placed in the resection gap. In addition, a vascularized or nonvascularized fibula can supplement the fusion.

Femoral turn-down (or tibial turn-up) arthrodesis has been described. This procedure uses half the distal femur or proximal tibia, which is transferred into the resection gap to fuse the knee. Implant arthrodesis has also been described with an intercalary prosthesis. Kuo et al. (66) published their account of a successful experience in fusing the knee with an intercalary porous titanium prosthesis.

Arthroplasty

Arthroplasty of the knee after resection of the femur or tibia is an alternative that has recently become popular. This reconstructive technique preserves functional knee motion. The biggest problem with this technique is durability. There are three ways to perform an arthroplasty of the knee after resection: (a) osteoarticular allograft arthroplasty, (b) allograft prosthetic composite arthroplasty, and (c) modular prosthetic arthroplasty. Each has advantages and disadvantages that need careful consideration.

The first two reconstructive techniques (Fig. 126.12) use biological tissue to restore either bone stock or bone stock with an articular surface. The osteoarticular allograft replaces the missing bone and, in addition, serves as a joint surface (22,43). It is critical to screen all biological tissue for both viral and bacterial contamination (43). Frozen osteoarticular allografts are procured from donors that meet the guideline(s) of the American Association of Tissue Banks. At the time of procurement from an acceptable donor, the allografts are cultured and viral screens are performed. There is some attempt to cryopreserve the articular cartilage of the donated joint using either glycerol or dimethylsulfoxide. The cartilaginous portion of the graft is immersed in one of these cryoprotective agents. Conceivably, at least, these chemicals will decrease the water crystal formation at the time of graft freezing, because crystal formation is believed to kill the chondrocytes and limit their preservation. With cryopreservation, at least a portion of the chondrocytes survive and can continue to produce proteoglycans and other cartilaginous matrix proteins after transplantation (132).

Arthroplasty of the knee after resection of the femur or tibia is an alternative that has recently become popular. This reconstructive technique preserves functional knee motion. The biggest problem with this technique is durability. There are three ways to perform an arthroplasty of the knee after resection: (a) osteoarticular allograft arthroplasty, (b) allograft prosthetic composite arthroplasty, and (c) modular prosthetic arthroplasty. Each has advantages and disadvantages that need careful consideration.

The first two reconstructive techniques (Fig. 126.12) use biological tissue to restore either bone stock or bone stock with an articular surface. The osteoarticular allograft replaces the missing bone and, in addition, serves as a joint surface (22,43). It is critical to screen all biological tissue for both viral and bacterial contamination (43). Frozen osteoarticular allografts are procured from donors that meet the guideline(s) of the American Association of Tissue Banks. At the time of procurement from an acceptable donor, the allografts are cultured and viral screens are performed. There is some attempt to cryopreserve the articular cartilage of the donated joint using either glycerol or dimethylsulfoxide. The cartilaginous portion of the graft is immersed in one of these cryoprotective agents. Conceivably, at least, these chemicals will decrease the water crystal formation at the time of graft freezing, because crystal formation is believed to kill the chondrocytes and limit their preservation. With cryopreservation, at least a portion of the chondrocytes survive and can continue to produce proteoglycans and other cartilaginous matrix proteins after transplantation (132).

Arthroplasty

Arthroplasty of the knee after resection of the femur or tibia is an alternative that has recently become popular. This reconstructive technique preserves functional knee motion. The biggest problem with this technique is durability. There are three ways to perform an arthroplasty of the knee after resection: (a) osteoarticular allograft arthroplasty, (b) allograft prosthetic composite arthroplasty, and (c) modular prosthetic arthroplasty. Each has advantages and disadvantages that need careful consideration.

The first two reconstructive techniques (Fig. 126.12) use biological tissue to restore either bone stock or bone stock with an articular surface. The osteoarticular allograft replaces the missing bone and, in addition, serves as a joint surface (22,43). It is critical to screen all biological tissue for both viral and bacterial contamination (43). Frozen osteoarticular allografts are procured from donors that meet the guideline(s) of the American Association of Tissue Banks. At the time of procurement from an acceptable donor, the allografts are cultured and viral screens are performed. There is some attempt to cryopreserve the articular cartilage of the donated joint using either glycerol or dimethylsulfoxide. The cartilaginous portion of the graft is immersed in one of these cryoprotective agents. Conceivably, at least, these chemicals will decrease the water crystal formation at the time of graft freezing, because crystal formation is believed to kill the chondrocytes and limit their preservation. With cryopreservation, at least a portion of the chondrocytes survive and can continue to produce proteoglycans and other cartilaginous matrix proteins after transplantation (132).
The sizing of an osteoarticular allograft is critical. Prior to resection of the distal femur or proximal tibia, take radiographs with a ruler to ensure proper fitting. If methylmethacrylate is used, inject it into the medullary canal of the distal femur anteriorly and posteriorly. If dynamic compression plating is performed, use two plates at 90° to improve the strength of the construct. Distal femoral allografts are usually fixed with plates placed laterally and anteriorly. Try to obtain six to eight cortices of screw fixation in each fragment through each plate. Fill any drill hole in the allograft with a metallic screw, because empty holes tend to be sites of revascularization and resultant stress fracture. After fixing the allograft to the host bone, restore the joint ligaments. It is important when requesting the graft from the tissue bank to specify grafts with joint capsule and collateral ligaments. Perform a circumferential repair of the capsular and collateral ligaments with nonabsorbable sutures or staples.

Cruciate ligament reconstruction is a controversial issue. Some authors believe that joint stability is markedly enhanced with anterior and posterior cruciate ligament reconstruction, whereas others believe it is not necessary when a solid circumferential capsular and collateral ligament repair is done. Standard cruciate ligament reconstructive procedures can be performed on osteoarticular allografts as described in Chapter 86 and Chapter 90.

Complications with Osteoarticular Allografts Osteoarticular allograft is a pure biological solution to the problem of joint restoration after tumor surgery. As a result, it avoids implant complications and potentially restores bone stock. There are, however, numerous complications associated with osteoarticular allografts (74). First, a significant nonunion rate (approximately 10%) at the allograft-host bone junction has been reported, especially in patients receiving chemotherapy. For example, Capanna et al. (16) published the Rizzoli experience with allograft nonunion. The highest incidence of nonunion was at diaphyseal junctions (50%). More than 90% of the cortical cancellous junctions healed. The authors observed that a gap between allograft and host bone was a contributing factor to nonunion. Autogenous grafting of the allograft-host bone junction was also recommended. If a nonunion develops, autogenous grafting at the allograft-host bone junction is usually necessary.

Another complication associated with an osteoarticular allograft is fracture (131). The reported incidence of allograft fracture is around 10%. Berrey et al. (9) classified the types of fractures seen with allografts: type I is rapid graft dissolution, type II is diaphyseal fracture, and type III is joint fragmentation. They successfully treated 80% of their allograft fractures without removing the graft. These fractures can occur at any time after implantation, and they are prone to occur at sites of revascularization or screw holes. These fractures can be either joint surface, metaphyseal, or diaphyseal. Although some allograft fractures can be managed nonoperatively, the majority require either bone grafting or a repeat osteoarticular allograft procedure.

Joint degeneration is another problem with osteoarticular allografts. Although there is a potential for maintenance of the viability of some chondrocytes during the freezing process, joint degeneration will inevitably occur. This can be minimized by avoiding incongruity of the joint with proper fitting. But even with a well-fitted allograft, joint degeneration occurs and is sometimes asymptomatic. Some degeneration may be the result of ligament instability. The symptomatic patients with joint degeneration will require a repeat arthroplasty. If the joint degenerates, it is feasible to use the osteoarticular allograft bone stock and simply do a resurfacing arthroplasty.

Allograft Prosthetic Composite Arthroplasty Allograft prosthetic composite arthroplasty of the knee is a combination of biological and implant reconstruction (Fig. 126.14, Fig. 126.15). This procedure replaces the resected bone tissue with a frozen allograft but, in addition, resurfaces the joint with a metallic prosthetic device (44,50). The allograft-host bone junction needs to be rigidly stabilized, as in an osteoarticular allograft. This can be accomplished either with a long-stemmed femoral prosthetic component that bridges the junction or with the use of dynamic compression plating. The choice of prosthetic device can range from a constrained rotating hinge to a less constrained device. The latter requires careful soft-tissue reconstruction, as in an osteoarticular allograft, but it does not require cruciate ligament reconstruction.

Figure 126.15. A: AP radiograph of an 18-year-old man with a malignant fibrous histiocytoma of the upper tibia. B: Lateral radiograph demonstrates bone destruction. C: AP radiograph after resection (intra-articular) of the upper tibia. The knee is reconstructed with an allograft and rotating hinge prosthesis. Note the staples repairing the patellar ligament.
The advantage of an allograft prosthetic composite arthroplasty is the restoration of bone stock by the allograft and the maintenance of the medullary canal of the host bone without bone cement. This is an advantage over the modular oncology device, which is fixed by a long medullary stem in bone cement. Theoretically, at least, an allograft prosthetic composite arthroplasty is easier to revise than a modular oncology device because there is no cement in the femoral medullary canal. Still, healing at the allograft-host bone junction can be a problem, especially with chemotherapy, but it provides better joint stability than an osteoarticular allograft because of the bearing surfaces of the prosthesis.

Modular oncology implants are now available (10,64), and they can replace the missing bone with metallic components that can be assembled in the operating room, but they have a constrained knee articulation (Fig. 126.16, Fig. 126.17 and Fig. 126.18). Most of these are a variation of the kinematic rotating hinge knee. This type of articulation allows for varying amounts of rotational freedom through a tibial bearing, and for flexion and extension through a hinge axle mechanism between the tibial and femoral components. These devices are usually fixed to the host bone with cemented intramedullary stems. They do have the option of a porous collar where extracortical bone fixation can occur. Their primary method of initial fixation, however, is the cemented intramedullary stem. The femoral modular oncology device can replace any amount of femur resected. In fact, these devices can replace the entire femur with both a hip articulation and a knee articulation.

**Figure 126.16.** Modular oncology prostheses. A: Femur. B: Tibia.

**Figure 126.17.** A: AP radiograph of distal femur of an 18-year-old woman. The osteosarcoma is difficult to see. There is an area of sclerosis by the medial femoral condyle. B: Lateral radiograph. There is medullary sclerosis and loss of the anterior cortex. C: Technetium bone scan shows intense activity in the distal femur. D: Transverse MRI (T1-weighted). The osteosarcoma replaces the medullary bone with a large soft-tissue mass. E: Coronal MRI (T1-weighted). The medullary extent of the tumor is precisely visualized. F: AP chest radiograph. Note the intravenous catheter for chemotherapy. G: AP radiograph after resection of the distal femur (intra-articular) and modular oncology prosthesis.

**Figure 126.18.** A: AP radiograph of 17-year-old girl with osteosarcoma of the proximal tibia. Note the sclerotic tumor in the medial tibial condyle. B: Lateral radiograph of the tibial osteosarcoma. C: AP radiograph after resection of the proximal tibia (intra-articular) and modular oncology tibial prosthesis. D: AP radiograph of the tibial shaft. Note the cemented intramedullary stem.

The modular oncology prosthesis has the fewest short-term complications. It provides for immediate bone restoration and stability (17,110). Bone healing does not need to occur. The modular oncology prosthesis allows early restoration of function with immediate weight bearing. In addition, joint stability is provided by the rotating hinge mechanism. Its potential disadvantage is long-term disability. Any part of the articulation can break by either yield failure or fatigue failure. The intramedullary stems can loosen and also can fracture.

Kawai et al. (55) reviewed 40 patients with prosthetic replacement of the knee after resection for malignant bone tumors. Their median follow-up was 8 years (range, 5–17 years). Implant survivorships were 85%, 67%, and 48% (at 3, 5, and 10 years). The complication rate was 45%, with aseptic loosening of the femoral component being the most common problem. Others (21,31,51,93,147,148) have reported 5-year implant survivorships ranging from 63% to 90%. These reports, however, had shorter follow-ups (34–77 months, mean). Despite potential problems, modular oncology prostheses represent the most popular method of performing a knee arthroplasty after resection of the knee.

The options for tibial reconstruction are identical to femoral reconstruction (139). There are, however, two major differences (11). First, soft-tissue coverage of a tibial reconstruction is critical. Soft-tissue coverage can be accomplished by either local rotation flaps or free flaps. Relying simply on skin to cover a tibial reconstruction is associated with a high complication rate. A second difference for tibial reconstruction is the problem of restoring the quadriceps mechanism (41,52,106). Because the upper end of the tibia is resected, the patellar ligament needs to be reattached to restore the function of the quadriceps mechanism. This can be accomplished either by the use of an allograft to which the patellar ligament can be reattached or by a local muscle rotation flap to which the patellar ligament can be reattached. This latter procedure is frequently performed for patients reconstructed with a modular oncology prosthesis.

An expandable prosthesis is available for skeletally immature patients (60,61,136) (Fig. 126.4). This metallic device allows a lengthening expansion as needed for skeletal growth (89). However, children have to return to the operating room on a fairly regular basis to lengthen the device, and this follow-up surgery can be associated with significant morbidity. Frequently, scar needs to be released to allow the lengthening mechanism to work. Complications such as infection, loosening, implant breakage, and flexion contractures have been reported with the expandable knee prosthesis (59,60) and (61,134). Kenan and Lewis (61) reviewed their experience with an expandable endoprosthesis for 40 children with bone tumors. Of these 40 patients, 20 were followed at least 5 years, and 18 of the 21 required revision. The mean implant survivorship was 68 months for cemented devices. There was a high complication rate in this series, and most patients developed stiffness of the knee. Ward et al. (148) reported similar results with an expandable prosthesis. It should be considered experimental, and more time is needed to prove its safety.
and effectiveness.

In conclusion, limb salvage about the knee is an effective procedure and a viable alternative for the treatment of malignant tumors. There are several options of reconstruction, each with advantages and disadvantages. The long-term durability of these reconstructions is still questionable. It is important to pay very careful attention to technical detail to ensure an acceptable outcome. Complications need to be anticipated and treated aggressively. Patient satisfaction with limb salvage for tumors about the knee appears to be good, and this in turn encourages oncologic surgeons to continue with this form of treatment.

SOFT-TISSUE COVERAGE ABOUT THE KNEE AFTER LIMB-SPARING TUMOR RESECTION

Principles of Soft-Tissue Reconstruction

Unlike limb-sparing surgery about the knee region, which has had many new developments and changes in surgical techniques, the principles of soft-tissue reconstruction remain remarkably constant. The main goal is to promote uncomplicated primary wound healing. The wide oncologic resection of the tumor and subsequent orthopaedic reconstruction of the bone or joint defect interrupts major regional blood vessels, depriving the wound margin of its axial blood supply (105).

The tenuous vascularity of these flaps and the creation of a large defect with potential dead space, combined with the variable location of the prosthesis, demands reliable, well-vascularized, durable, and flexible soft-tissue coverage. It is important to emphasize that tension-free closure of the defect must be obtained and dead space obliterated, which makes it necessary to add more tissue. To achieve this, local muscle transposition has been the mainstay of soft-tissue reconstruction, with distant microvascular free tissue transfer and fasciocutaneous flaps used when necessary (62).

The most common and potentially limb-threatening complications of these limb-sparing procedures include failure of wound healing, flap necrosis, and infection, which can unacceptably lead to exposure of the prosthesis or loss of the limb (79,109). Many patients receive preoperative adjuvant chemotherapy or radiation therapy, and they are therefore immunosuppressed and have decreased wound-healing capabilities at the time of surgery (59). Satisfactory postoperative soft-tissue healing is absolutely required to resume chemotherapy and/or radiation if necessary. Obviously, serious complications involving soft-tissue coverage can have serious effects. Problems such as infection; exposure of the implant; and withholding of chemotherapy, radiation therapy, or antithrombotics threaten a successful result from the limb-sparing surgery and even the patient's life. Complications increase the length of hospital stay and delay ambulation and range-of-motion (ROM) exercises, increasing the possibility of loss of some limb function.

To obtain stable, well-vascularized, and, in select cases, even functional soft-tissue reconstruction, total muscular envelopment of the exposed bone and the joint prosthesis (metal, plastic, allograft, or homograft) is necessary. Local muscle flaps using the medial and lateral gastrocnemius, soleus, portions of tibialis anterior, flexor digitorum longus, and flexor hallucis longus are most commonly used for this soft-tissue reconstruction. The medial gastrocnemius muscle serves as the mainstay of muscle reconstruction (46,68,113). The muscle is readily available in the operative field, has a reliable vascular supply (one of the most predictable of all lower extremity muscle flaps), and is of sufficient size to cover the majority of knee defects (73). It is possible to enlarge coverage by scoring the fascia of the muscle; splitting the muscle; augmenting the muscle envelope with adjacent muscles such as portions of the tibialis anterior, soleus, and flexor digitorum longus; or a combination of these methods. If necessary, converting to a medial gastrocnemius island flap can enhance the versatility of coverage, size, and location (3). The gastrocnemius muscle has the additional benefit of providing a well-vascularized segment of tendon that can be used for extensor reconstruction about the knee. In our own patients, using the gastrocnemius muscle for reconstruction has been very successful in providing excellent knee extension with normal gait.

We use free-muscle transfer flaps readily when larger defects dictate their use (117,146). The latissimus dorsi is the first choice for free-muscle transfer because of its size, reliable vascular supply, ease of harvesting, and large, lengthy pedicle (143). It also has an optional, extremely predictable skin paddle that offers good protection from radiation and trauma. The tendinous portion of this muscle also can be used for extensor reconstruction about the knee. Other free-transfer options include the rectus abdominus and the gracilis muscles. All of these muscle flaps, both local and distant, have been successfully used without causing significant donor site functional deficits. This is especially true of the medial and lateral gastrocnemius muscles, the soleus muscle, and the tibialis anterior and flexor digitorum muscles when partially transferred in the proper fashion. In the pediatric age group, there have been no deleterious effects at either the donor or recipient sites with subsequent growth and development.

The majority of defects are covered with muscle and split-thickness skin grafts, which give an acceptable cosmetic result. We discourage the use of a composite myocutaneous flap of the gastrocnemius muscle. Donor site closure is extremely difficult; it limits the use of the muscle in tendon reconstruction, and it decreases its excursion and coverage area. Finally, lateral fasciocutaneous flaps can be used selectively to cover smaller areas or in patients whose local muscle flaps are insufficient for total coverage and whose medical conditions contraindicate a lengthy microvascular free muscle transfer (48,158). See Chapter 8 and Chapter 35 for more details.

OPERATIVE TECHNIQUE

Preoperative Planning

Cooperative preoperative planning that involves both oncologic and reconstructive surgeons is essential to determine the amount of tissue to excise and how to deal with scars and zones of irradiated and injured tissues (4). The timing of surgery and dosages of chemotherapy and radiation therapy must be coordinated with the oncologist and radiation therapist as well, particularly concerning the dates when platelet, red blood cell, and white blood cell counts reach their lowest points. Perform angiograms (a necessity for free-tissue transfer and myocutaneous flap cases) at least 48 hours prior to surgery, and catheterization entrance sites must be through an uninvolved extremity. Administer appropriate preoperative antibiotics, insert a Foley catheter, and take care to protect peripheral nerves and pressure points (especially the heels) with padding during this long operative procedure.

Intraoperative Procedure

- Widely excise all areas of involved skin and incision sites, taking special attention to elevate the adjacent skin as fasciocutaneous flaps to decrease ischemia (79).
- After excising the tumor and bone completely, examine the knee region for its remaining blood supply.
- Dissect the nicely exposed deep portion of the gastrocnemius muscle at this time, if desired (Fig. 126.19). Identify the sural arteries and veins and dissect them back to their popliteal artery to obtain a sufficient pedicle length or if using an island flap. Take care to preserve and protect these structures, as 3–5 mm vessels are the main vascular pedicles to the gastrocnemius muscles.
- At this point, if possible, close the soft tissues posterior to the prosthesis or arthrodesis. This includes the origins of the gastrocnemius muscles proximally, and the tibialis posterior to the soleus muscles more distally (78).
- Obtain hemostasis, and irrigate the tissues with antibiotic solution.
- After the prosthesis is in place, dissect the remainder of the gastrocnemius muscle. If necessary, a second, "stocking seam" longitudinal incision midposteriorly can be helpful during harvesting of the medial gastrocnemius muscle (46). The most tenuous blood supply is to the medial fasciocutaneous flap, and this can be improved if the stocking seam incision is made parallel and distal, leaving as wide a skin bridge as possible.
- To reconstruct the extensor mechanism, attach the patellar tendon remnant to the loop on the tibial component using heavy #5 nonabsorbable sutures.
- With the knee at neutral flexion, attach the tendon snugly to set proper quadriceps tension (Fig. 126.20A). This sutured reattachment now serves as the foundation for the extensor reconstruction.

Figure 126.19. Exposed defect of the knee region after tumor resection.
Next, rotate the medial gastrocnemius muscle into position, scoring the muscle’s overlying anterior fascia so the muscle spreads to fill the defect. Suture the tendinous portion of the muscle under an axial (now posterior) proximity (along the top) to the loop and to the remnants of the patellar tendon in a “vest-over-pants” fashion using #2 nonabsorbable interrupted sutures. Leave the suture ends open and secured by hemostats to assist in placement. Suture the medial hamstrings to this tendon as well, with the final portion of the gastrocnemius muscle sutured to the remaining lateral bicipital peristeum and iliotibial bands (Fig. 126.20C).

If additional tendon graft is required to aid in extensor mechanism reconstruction, use an extended medial gastrocnemius flap, including the medial portion of the Achilles tendon (54). All remaining portions of the prosthesis or arthrodesis are now covered with the adjacent muscles, thereby forming a complete muscular envelope.

Laterally, portions of the bicipital anconeus can be advanced or even split off to preserve function if the tendon and a sufficient portion of muscle are left attached. On the medial side of the ilia, the soleus muscle proximally—portions of the flexor digitorum longus and flexor hallucis longus muscles distally, if necessary—can be sutured to the lateral musculature, completing the muscular encasement (Fig. 126.20C).

Advance the fasciocutaneous flaps developed at the beginning of the surgery and suture them free of tension into position, tucking the muscle flaps underneath with tie-over bolsters if necessary. Because uncomplicated primary wound healing is of paramount importance, we have found it best to resed any questionably viable flap edges, releasing tension from these flaps whenever possible, even if it means grafting larger portions of muscle.

Graft the remaining exposed muscle with meshed split-thickness (0.012 inches thick) skin grafts harvested from the lateral upper thigh region and sutured in place with 5-0 rapidly absorbing sutures (Fig. 126.20D). Using two large hemovac drains to prevent hematoma, dress the grafts and flaps, and apply a posterior splint from toes to upper thigh.

**Postoperative Care**

Check pulses before leaving the operating room, and temporarily discontinue epidural catheter solutions in the postanesthetic recovery room to assess motor function. The muscle flaps are sensitive, and patients do feel referred pain posteriorly when the transposed gastrocnemius muscle is palpated. If the pain is extreme, take down the dressings to rule out hematoma, pressure on the flap, or muscle ischemia. Keep the patient at strict bed rest with the leg slightly elevated and the posterior splint in place for approximately 5 days while postoperative wound checks and dressing changes are performed. If the flaps are viable, there is no bleeding, and the swelling is resolving, place the knee in nearly full extension in a windowed cast and discharge the patient at 5–7 days postoperatively. If possible, fit a knee–ankle foot orthosis prior to discharge for later use. Allow the patient up out of bed at 2 weeks postoperatively, and chemotherapy or radiation therapy may start 3 weeks postoperatively if primary healing is complete or if there is no drainage and only small superficial wounds remain.

Following this particular knee arthroplasty, it is important to prevent an extensor lag; therefore, avoid immediate postoperative motion (78). Start knee flexion exercises at 8 weeks postoperatively if wound healing is uncomplicated. If an extension lag develops, then immobilize in extension for another 4–6 weeks. Use a knee–ankle–foot orthosis until adequate active extension of the knee is present, which is usually at 4–6 months.

**COMPLICATIONS**

The most common and one of the most deleterious complications is wound necrosis (19,30,109). At times the diagnosis can be difficult. In our experience, violaceous discoloration of the large fasciocutaneous flaps is an ominous sign and uniformly leads to necrosis. Intraoperative marking of the level of the prosthesis or the allograft on the skin surface can help future management decisions. Surgical debridement with secondary reconstruction is recommended as soon as the necrosis is established. Perform all significant debridements in the operating room; they should not be taken lightly. Debridment, if performed during the first several days, can have excellent results (46,87). If the necrosis extends down to the prosthesis or allograft, copiously irrigate with antibiotic solution using a pulsatile evacuator. Then do a new reconstruction with flap readvancement, skin grafting, or new muscle flaps, including free-tissue transfer if necessary.

Additional complications include nerve injuries, which in most cases are a neurapraxia and resolve with time (109). In some cases, arterial spasm is present. If pulses remain absent postoperatively, and arteriograms may be required during the first 6 hours to rule out vascular injury or thrombosis. During the course of tumor extirpation, if nerve segments or blood vessels require resection, immediate reconstruction is recommended. Saphenous vein and sural nerve grafts are readily available in the operative field; take care to cover all grafts with anastomosed muscle. Pressure necrosis can be problematic, and meticulous padding of pressure points is necessary, starting with the preoperative period through the postoperative cast and splinting. The operative limb has altered blood and nerve supply and is more susceptible to pressure necrosis.

In our group of patients, infection has been conspicuously absent. This could be explained by the use of perioperative antibiotics, vertical laminar airflow operating rooms with personal exhaust suits for all members of the surgical team, and full muscular closure over the prosthesis and development of fasciocutaneous flaps, with prompt management of zones of wound necrosis (109).

**TUMORS OF THE SHOULDER GIRDLE**

Each bone of the shoulder girdle—the proximal humerus, the scapula, and the distal third of the clavicle—can give rise to a primary malignant bony tumor or be involved by an adjacent soft-tissue sarcoma (23). The proximal humerus is one of the most common sites for high-grade malignant bony tumors in both adults and children, and it is the most common site for osteosarcoma. Chondrosarcoma, which commonly involve the shoulder girdle, often arise from the scapula or the proximal humerus. The bones of the shoulder girdle may also be involved secondarily by high-grade soft-tissue sarcomas that often require resections similar to that used in the surgical treatment of high-grade primary bony sarcomas with an extraosseous component.

Metastatic tumors often involve the shoulder girdle, and because of the extent of bony destruction and the presence of large extraosseous components, the treatment is sometimes similar to that for primary malignant bony sarcomas. This pattern is most common with the hypernephromas (renal cell carcinomas), which have a unique propensity to involve the proximal humerus, as an solitary metastasis.

The resection of a malignant bony tumor of the shoulder girdle with subsequent shoulder-girdle reconstruction consists of three stages (75):

1. Wide surgical resection of the tumor using the principles already discussed
2. Reconstruction of the skeletal defect following the principles of orthopaedic skeletal reconstruction
3. Multiple muscle transfers to cover the skeletal reconstruction and to provide stability of the shoulder girdle and support for the extremity

The aim is to provide a stable shoulder girdle with a functioning elbow. The various surgical techniques currently in use for reconstruction of a segmental defect of the humerus or shoulder girdle all offer some degree of stability, function, durability, ROM, and preservation of motor power.

**OVERVIEW AND HISTORY**

Initial reports of shoulder-girdle resections were confined to the individual bones or portions of the scapula. The first mention of a scapular resection in the literature is a partial scapulectomy that Liston performed in 1819 for an ossified aneurysmal tumor (46). In 1837, Mussey treated a recurrent chondrosarcoma by glenohumeral disarticulation (54). Syme performed a near-total scapulectomy with resection of the clavicle for a tumor in 1856 (129). This is the first reported total scapulectomy. In
shoulder-girdle surgical anatomy. Frequently, the local anatomy of a sarcoma determines the extent of the operative procedure required. The following discussion addresses unique considerations of MM.

Cartilage of the glenohumeral joint. An extra-articular resection is often required to perform a safe limb-sparing procedure. (From Sugarbaker PH, Malawer MM. Musculoskeletal Surgery for Cancer: Principles and Techniques. New York: Thieme Medical, 1992: Chapter 27, with permission.)

In 1965, Papioannou and Francis described a three-part classification for scapulectomies: (a) total scapulectomy and nearly total scapulectomy, (b) radical subtotal scapulectomy, and (c) subtotal or partial scapulectomy. In 1968, Samilson et al. revised this classification, adding the classical intrascapulothoracic resection (Tikhoff-Linberg procedure) and forequarter amputation, thereby establishing a universal classification system that covered virtually all major shoulder-girdle operations (resections and amputations) as of that date.

Since then, a number of new procedures and modifications of shoulder-girdle resections have been developed. Most have been reported as Tikhoff-Linberg resections or modified Tikhoff-Linberg resections, inaccurate eponyms for the procedures performed. The Tikhoff-Linberg resection was never intended to refer to resections of major tumors of the humerus; its originators intended it to be used only with intrascapulothoracic resections for sarcomas of the scapula and the periscapular soft tissues.

These two classification systems, however, are purely descriptive and refer almost exclusively to the bone resected. They do not accommodate or reflect the new concepts and terminology that have developed in orthopaedic oncology during the past two decades. To fill this gap, Malawer et al. have described a six-stage surgical classification system (75,77,80,81). This system is based on current concepts of surgical margins, the relationship of the tumor to anatomic compartments (i.e., intracompartamental versus extracompartamental), the status of the glenohumeral joint (intra-articular versus extra-articular), the magnitude of the individual surgical procedures, and the presence or absence of the abductor mechanism (deltoid muscle, rotator cuff muscle, or both). The six-stage classification is as follows. (Fig. 126.214 illustrates the classifications, and Fig. 126.21B shows the distribution of 72 shoulder-girdle resections.)

**Figure 126.21.** A: Classification of shoulder-girdle resections. B: Distribution of 72 shoulder-girdle resections for bone tumors. (From Malawer MM, Meller I. A New Surgical Classification System for Shoulder Girdle Resection: Analysis of 38 Patients. Clin Orthop 1981;267:33, with permission.)

| Type I: Intra-articular proximal humeral resection |
| Type II: Partial scapular resection |
| Type III: Intra-articular total scapulectomy |
| Type IV: Intra-articular total scapulectomy and humeral head resection |
| Type V: Extra-articular humeral and glenoid resection |
| Type VI: Extra-articular humeral and total scapulectomy |

Each type is further modified according to a major variable: the presence or absence of the main motor group, the abductor mechanism (deltoid and rotator cuff muscle). The abductors are present (subtype A) or partially or completely resected (subtype B). The abductor mechanism is almost always resected when there is extensive extension of a bone tumor in this area. The loss of any component of the abductor mechanism (deltoid muscle or rotator cuff) tends to create a similar functional disability. Regardless of histology or primary bone involvement, subtype A generally entails an intracompartamental resection, and subtype B an extracompartamental resection.

**TUMOR INVOLVEMENT OF THE SHOULDER—UNIQUE SURGICAL AND ANATOMIC CONSIDERATIONS**

The shoulder joint appears to be more prone than other joints to intra-articular or pericapsular involvement by high-grade bone sarcomas. Figure 126.22 shows the mechanisms of tumor spread. Direct capsular extension, direct tumor tracking along the long head of the biceps, poorly planned biopsy, and pathologic fracture are mechanisms of glenohumeral contamination and make intra-articular resection for high-grade sarcomas a higher risk than extra-articular resection for local recurrence. (This is in contrast to most clinical experience with resections of the distal femur, which tend to be intra-articular.) Therefore, extra-articular resections are recommended for most high-grade sarcomas of the proximal humerus and scapula.

**Figure 126.22.** Mechanisms of local tumor spread for sarcomas of the proximal humerus. There are five mechanisms of tumor spread to the capsule, synovium, and cartilage of the glenohumeral joint. An extra-articular resection is often required to perform a safe limb-sparing procedure. (From Sugarbaker PH, Malawer MM. Musculoskeletal Surgery for Cancer: Principles and Techniques. New York: Thieme Medical, 1992: Chapter 27, with permission.)

Frequently, the local anatomy of a sarcoma determines the extent of the operative procedure required. The following discussion addresses unique considerations of shoulder-girdle surgical anatomy (Fig. 126.23).
Figure 126.23. Osteosarcoma of the proximal humerus. A: Angiogram of the proximal humerus showing large circumflex vessels supplying the tumor (arrows), which must be ligated prior to resection. B: MRI scan showing “skip” metastases (arrows) distal and not in continuity with the main mass. Skip lesions are seen in less than 5% of osteosarcomas and are best detected by MRI.

Often the glenohumeral joint is ineffective as a barrier to tumor spread. A lesion may cross the joint by direct extension or by other mechanisms, as shown in Fig. 126.24. It is often necessary to perform an extra-articular resection for high-grade bone sarcomas of the proximal humerus or the scapula (glenoid region).

Figure 126.24. Tumor involvement of the glenohumeral joint. A: CT scan of a large osteosarcoma of the scapula, which shows extensive involvement of the soft tissues with involvement of the glenohumeral joint. B: MRI scan of the same area, which shows marked involvement by the tumor surrounding and within the glenohumeral joint (white area, T2 pattern).

The three major cords of the brachial plexus are in close proximity to the subscapularis muscle, glenohumeral joint, and proximal humerus. Tumors involving the upper scapula, the clavicle, and the proximal humerus often displace the infraclavicular component of the brachial plexus, which then may make it necessary to sacrifice some of the major nerves.

The musculocutaneous and axillary nerves are often in contact with or in close apposition to tumors around the proximal humerus, and before proceeding with resection it is necessary to clearly identify both. The musculocutaneous nerve generally comes from beneath the coracoid and passes through the conjoined tendon or coracobrachialis muscle within a few centimeters of its origin. The position of this nerve does vary, however, and it may lay within 6–8 cm of the coracoid. It then passes through the short head of the biceps and into the long head of the biceps before innervating the brachialis muscle.

The axillary nerve is closest to most large tumors of the proximal humerus. It arises from the posterior cord and, along with the circumflex vessels, courses around the subscapularis muscle and the head and neck of the humerus to innervate the deltoid posteriorly. In patients who have large malignant tumors of the proximal humerus, the axillary nerve usually must be resected because of tumor proximity or involvement, and because it is necessary to remove the deltoid muscle to provide a satisfactory margin. With large, stage IIIB bone sarcomas of the proximal humerus, it is rare that the axillary nerve and deltoid muscles can be preserved.

The brachial artery is surrounded by the three major cords of the brachial plexus and is tethered to the proximal humerus by the anterior and posterior circumflex vessels. A presurgical angiogram is extremely useful to localize the brachial artery and identify the level of the circumflex vessels. Occasionally, one finds anomalous brachial and axillary arteries that would be difficult to identify and explore if not recognized preoperatively. In general, the circumflex vessels are ligated during the initial dissection; this allows the entire brachial artery and the vein and nerves to fall away from the tumor mass. Early ligation of the circumflex vessels is key to the resection of proximal humeral sarcomas.

The radial nerve courses along the posterior aspect of the axillary sheath and exits from the posterior cord at the inferior border of the latissimus dorsi muscle. Fortunately, most sarcomas are located in the proximal third of the humerus and do not involve this nerve. However, to avoid injury the radial nerve must be isolated and protected prior to tumor resection. Sacrifice of the radial nerve is rarely necessary.

PREOPERATIVE EVALUATION AND IMAGING STUDIES

Appropriate imaging studies are crucial to successful resection of tumors of the shoulder girdle (75, 77, 80, 81). The most useful preoperative evaluations are CT scans, MRI, arteriography, and three-phase bone scans (Fig. 126.25). For large tumors of the proximal humerus, a venogram may be warranted if there is evidence of distal obstruction.

Figure 126.25. Osteosarcoma of the proximal humerus: staging studies and intraoperative management by resection and modular prosthetic replacement. A: Plain radiographs showing a typical sclerosing osteosarcoma (arrows) of the proximal humerus. B: Bone scan demonstrating extent of the tumor. Note: There are no other bony sites of involvement. C: Angiogram after chemotherapy showing the axillary artery and the circumflex vessels without any evidence of tumor blush. The absence of tumor vascularity is an excellent indication of response of the tumor with marked tumor necrosis. D: Intraoperative photograph showing the Modular Replacement System (MRS, Howmedica, Rutherford, NJ). E: The postoperative radiograph following an extra-articular resection of the proximal humerus and the glenohumeral joint (type V resection).

A CT scan is more useful than an MRI in determining cortical bone changes, and it is considered complementary to an MRI in evaluating the chest wall, clavicle, and
axilla. Furthermore, the CT scan is more reliable than an MRI in the restaging of patients prior to surgery to determine the effects of induction chemotherapy, especially the bony response and the amount of tumor necrosis. It is also useful in determining the potential planes of tumor resection.

Use an MRI to determine the extent of soft-tissue involvement, especially around the glenohumeral joint, or of tumor extension along the chest wall or posterior scalp. It is often difficult to visualize the suprascapular area in patients with large tumors, which may infiltrate below the subcapsularis muscle and exit near the coracoid. An MRI is especially useful in identifying the extent of intracortical tumor, which is necessary to determine the length of the resection. Skip metastases rarely occur in this area. However, an MRI is not effective in determining the preoperative tumor response to induction chemotherapy.

The main purpose of a bone scan is to determine the intraosseous extent of the tumor defect and to evaluate for metastases. Both bone scan and MRI data are necessary to accurately evaluate intraosseous tumor extension.

Angiography is extremely useful and should be done with the arm abducted to determine the relationship of the brachial plexus and the vessels to the major tumor, the level of the circumflex vessels, and the presence of any anomalies. This is also the most reliable means of determining the response to neoadjuvant chemotherapy. The absence of vessels in the tumor or decrease in tumor vascularity indicates tumor necrosis. If there is a very good angiographic response (i.e., decrease or absence of tumor blush), it is safe to proceed with a limb-sparing resection, preserving as much normal tissue as possible and accepting close margins as long as they are negative.

If venous thrombosis or a mural thrombus is expected, perform venography. The most suspicious finding is extremity edema. Brachial vein thrombosis is most common with large shoulder osteosarcomas and chondrosarcomas.

INDICATIONS AND CONTRAINDICATIONS FOR SHOULDER-GIRDLE RESECTION

Because it is possible to treat approximately 95% of high-grade shoulder-girdle malignancies safely by limb-sparing surgeries (75), forequarter amputation is now rare. The decision to proceed with limb-sparing surgery is based on the location of the cancer and a thorough understanding of its natural history. Major contraindications are tumor involvement of either the neurovascular bundle or the chest wall. Relative contraindications include pathologic fracture, extensive involvement of the shaft of the humerus, infection, and tumor contamination of the operative area from hematoxia following biopsy or unwise placement of the biopsy incision. These contraindications are described next in greater detail (80).

The brachial artery is rarely involved by a tumor, although it may be in close proximity. The subscapularis and the short head of the biceps muscles often separate tumors of the proximal humerus and scapula from the vascular structures. Occasionally, however, the brachial veins are directly invaded by a tumor and may be the site of tumor thrombi.

Involvement of the musculocutaneous nerve by the tumor is rare, as is involvement of the three major cords to the brachial plexus, which follow the brachial vessels. Two of its major branches, the axillary nerve and the musculocutaneous nerve, however, may be involved, and resection of the axillary nerve is almost always required for large (stage IIIb) tumors of the proximal humerus. Direct tumor extension into the brachial plexus requires a forequarter amputation. Direct tumor extension into the plexus occurs most often with axillary or chest wall sarcomas.

If an inappropriate biopsy contaminates the shoulder girdle, limb-preserving resection is often inadvisable. Today, one of the major causes for amputation of the shoulder girdle is inappropriate biopsy resulting in contamination of the pectoralis major, the chest wall, and the neurovascular structures.

Another contraindication is infection. Even with adequate resection, reconstruction of an infected field by arthrodesis, prosthesis, or allograft replacement reconstruction is extremely risky, considering that all patients with high-grade sarcomas must receive postoperative adjuvant chemotherapy. If an infection cannot be eradicated with the primary resection, amputation is advisable.

Previous surgeries also affect the feasibility of a limb-sparing procedure. The local recurrence rate is increased if a wide resection is attempted following a previous resection around the shoulder girdle.

On rare occasions, tumors of the scapula or proximal humerus with large soft-tissue components may invade the chest wall and intermingle with the intracostal muscles and the ribs. This situation usually requires a resection of the adjacent chest wall, but it is not an absolute indication for forequarter amputation because limb-sparing resection may be combined with chest wall resection.

In the rare instance of lymph node involvement documented by biopsy, a forequarter amputation may be the best way to remove all the axillary nodes as well as the proximal sarcoma. On the other hand, it is not unreasonable to proceed with a limb-sparing resection and an axillary node dissection. This method can provide long-term cure and local control.

BIOPSY TECHNIQUE

Because 95% of bone sarcomas have a soft-tissue component, a small needle or core biopsy is possible (Fig. 126.26). One exception may be the young patient with a suspected round cell tumor for whom more tissue for cytogenetic and immunohistochimical stains may be required. Another exception would be an older patient in whom a solitary metastatic lesion is suspected, and the pathology supports either metastatic carcinoma or a spindle cell sarcoma. This differentiation most often occurs with metastatic renal cell carcinoma. In such a case, a significant amount of tissue may be required to obtain immunohistochimical stains that will differentiate the metastatic tumor from a primary sarcoma.

![Figure 126.26](https://example.com/image126.26)

**Figure 126.26.** Technique of biopsy of tumors of the proximal humerus. A: Schematic diagram showing a core needle biopsy through the anterior one third of the deltoid. Note: The axillary nerve comes in posteriorly, so the deltoid can be preserved if necessary. This does not contaminate the deltopectoral interval and thus the brachial vessels if a resection is required. B: Clinical photograph showing puncture site following a core needle biopsy (arrow). This patient had a high-grade osteosarcoma and was treated by an extra-articular shoulder-girdle resection. C: Plain radiograph showing the technique utilized if a small incisional biopsy is required. A 1 inch incision is utilized. A curet removes a small amount of tumor and the defect in the bone is filled with polymethylmethacrylate. The bone cement acts like a cork to prevent contamination following an open biopsy.

Most shoulder-girdle soft-tissue sarcomas are easily palpable. Multiple core needle biopsies performed through one puncture site under local anesthesia are recommended. If the mass is not palpable, perform all needle or core biopsies under fluoroscopic or CT guidance. To obtain multiple cores with only one puncture site, reintroduce the needle through the same puncture site, but vary the angle to obtain cores from several different areas. Obtain cultures routinely, regardless of the suspected diagnosis, because infection may simulate any malignancy. Touch-preps, frozen sections, or both confirm that lesional tissue has been obtained.

When an open (incisional) biopsy of the proximal humerus is required, perform it through the anterior third of the deltoid, not through the deltopectoral interval (75,61). A biopsy through the anterior third of the deltoid results in a limited hematoma that is confined by the deltoid muscle and can be resected with the tumor en bloc. On the other hand, an open biopsy through the deltopectoral interval will contaminate the pectoralis major muscle and provide a plane for the hematoma to dissect to the chest wall along the brachial vessels. This makes a local resection more difficult and increases the possibility of local recurrence.
Perform biopsies of scapular tumors along the lateral or axillary border of the scapula or along the intended site of the resection incision, and perform biopsy of the clavicle along the length of the clavicle. Unless there is a soft-tissue component, a small biopsy is advisable because a needle in this location could injure the brachial plexus and the neurovascular bundle.

REHABILITATION AFTER SHOULDER-GIRDLE RESECTION

Patients undergoing shoulder-girdle resection retain hand function and good elbow function, but they lose some shoulder function, mainly abduction. From a rehabilitation perspective, the outcome of resection is clearly superior to that of a forequarter amputation or shoulder disarticulation. Furthermore, shoulder-girdle resection is less disfiguring and is associated with only minimal pain and edema. Generally, patients’ acceptance of the outcome of their surgery is good to excellent.

Rehabilitation begins with an orientation program that often features pictures of patients who have undergone the procedures, and demonstrations of what one can do postoperatively. Preoperatively, a shoulder mold is fashioned using the involved shoulder, provided its contours are not distorted. The cosmetic shoulder helps to preserve the symmetry and appearance of the shoulder contour and can support a bra strap or heavy overcoat.

Have the patient use a sling postoperatively, and restrict motion until the incision is healed. Remove sutures after about 2 weeks. Control edema with an elasticized glove or elastic stockinet. At the same time, have the patient begin active, maximal head motion to preserve strength and range and to help mobilize edema.

If the incision heals per primam, start assistive elbow motion within the confines of the sling as soon as the suction catheters have been removed. At about 2 weeks, remove the sling for passive shoulder ROM and pronation and supination of the wrist. Have the patient continue to use the sling intermittently after the incision is healed, primarily for upright activities in which arm support increases comfort. Once his arm is out of the sling, have him perform full ROM of elbow (flexion, extension, pronation, and supination). He should also begin passive ROM to the shoulder (flexion, abduction, and external and internal rotation and pendulum exercise) with the help of a family member or physical therapist.

Rehabilitation depends on the type of reconstructive technique. In general, patients with endoprosthetic intra-articular allografts or composite allograft reconstruction undergo the same rehabilitation program. Those treated by arthrodesis, by allograft, or by autograft reconstruction are immobilized for 4–5 weeks to allow early bony union to take place.

TUMORS OF THE SCAPULA AND PERISCAPULAR AREA

CLINICAL CHARACTERISTICS

Tumors of the scapula present with pain, a mass, or both, and they may become quite large before they are brought to your attention. The most common primary malignancy of the scapula is the chondrosarcoma. Secondary chondrosarcomas occur from an underlying osteochondroma, but fewer than 2% of osteosarcomas arise from the scapula. In children, the most common malignant scapular tumor is Ewing’s sarcoma. Soft-tissue sarcomas may involve the supraspinatus or the infraspinatus musculature and, secondarily, the scapula. Most soft-tissue sarcomas of the scapular region occur in adults. In very rare cases, radiation sarcomas of the scapula may develop secondary to radiotherapy for breast carcinoma.

Among the unique anatomic considerations is the fact that during the early stages of development, a cuff of soft tissue surrounds tumors arising within the scapula (75,79,80,81). As sarcomas enlarge, they may develop a large axillary component and invade the axillary vessels and brachial plexus. Tumors arising from the neck or clavicle usually involve the periscapular tissue and the glenohumeral joint; this is especially true of chondrosarcomas, osteosarcomas, and Ewing’s sarcoma. Important anatomic areas to evaluate for extension are the chest wall, the axillary vessels, the proximal humeral and periscapular tissues, and the rotator cuff. Also, examine the axillary lymph nodes carefully, even though they are usually negative. Large supraspinacular tumors extend into the anterior and posterior triangles of the neck, making resection difficult or contraindicated except for palliation.

A CT scan and MRI are the most valuable means of determining the size and extent of extraosseous disease and its relationship to the chest wall, whereas arteriography is important to determine vascular involvement. Displacement of the axillary vessels indicates anterior (axillary) extension of a tumor. Bone scans may show rib involvement or proximal humeral extension.

The biopsy site is a crucial factor in determining the final operative procedure, because inadvertent contamination of the neurovascular structures or chest wall must be avoided. For tumors arising within the body of the scapula, perform a posterior needle biopsy or a biopsy along the anterior axillary border of the scapula. With lesions involving the scapula and neck, choose a posterior approach directly through the posterior deltoid and teres minor; avoid an anterior approach. If an open biopsy is required, we recommend a small longitudinal incision in line with the incision that will be used for resection. Most operative approaches involve an incision along the axillary border of the scapula.

Certain specific tumors of the scapula and periscapular area require special management (Table 126.1) (75). Chondrosarcomas, for example, commonly arise from the scapula. Therefore, approach any large cartilaginous lesion of the scapula in an adult with a high index of suspicion. These lesions tend to be low grade with a large extraosseous component, and they are usually an Enneking stage IB. Cartilage tumors approaching the glenohumeral joint may directly involve the joint space and readily implant on the articular cartilage. In such cases, an extra-articular resection is generally recommended, with no attempt to perform an intra-articular resection. Usually a Tikhoff-Linberg resection (type IV) is curative.

Table 126.1. Histogeneseis and Anatomic Site of Tumor in 72 Patients Treated by Limb-Sparing Surgery of the Shoulder Girdle

Osteosarcomas (72), of which about 1.5% occur in the scapula, require a limb-sparing resection (type IV) or forequarter amputation. The limiting factors in performing a limb-sparing procedure are the size and extent of the extraosseous component. Neurovascular involvement requires a forequarter amputation. Evaluate chest wall involvement before surgery; if present, a partial chest wall resection en bloc with ablation of the primary tumor is necessary.

The traditional treatment for Ewing’s sarcoma arising in the scapula has been radiation therapy in conjunction with chemotherapy, with excellent functional results. However, the treatment of Ewing’s sarcoma is undergoing reevaluation. Recently, total scapulectomy (type IIIA or B), with or without prosthetic replacement, has been recommended in lieu of radiation therapy (74). Surgery has become increasingly common with the hope of increasing local control, decreasing the morbidity of radiation (especially of late secondary osteosarcomas), and increasing patient survival. Plan the surgery after induction chemotherapy, and stage the patient and the local tumor area as with patients who have other high-grade sarcomas.

It is usually possible to treat soft-tissue sarcomas arising in the periscapular musculature satisfactorily by removing the adjacent tissue en bloc while preserving the scapula, then following with radiotherapy. Occasionally, a soft-tissue sarcoma arising from the deeper structures will involve or encase the scapula, requiring combined scapular resection. If the tumor is distal to the scapular spine, a partial (type IIIB) or total (type IIIB) scapulectomy may be adequate. Involvement of the supraspinal musculature or rotators requires an extra-articular resection (type IV).

Giant cell tumors and aneurysmal bone cysts often cause marked ballooning and destruction of the scapula. Small lesions may be treated by intraleosseal curettage. If the neck of the scapula is not involved, it is possible to perform a partial scapulectomy with minimal loss of function. Treat large lesions with total scapulectomy (type
III A) while preserving most adjacent muscles. Reconstruction involves suspending the scapula from the clavicle by a static and dynamic reconstruction. This is an excellent indication for scapular prostheses, which have recently been developed.

OPERATIVE TECHNIQUES

The Tikhoff-Linberg procedure (extra-articular total scapular proximal humeral resection, type IV) consists of en bloc removal of the scapula, clavicle, and proximal humerus and preservation of the arm (75,77,80,86) (Fig. 126.27). Indications for the procedure are low- and high-grade scapular sarcomas and periscapular and supraspacular soft-tissue sarcomas. A careful preoperative evaluation is imperative. A CT scan and MRI can help to determine possible chest wall involvement, and angiography is crucial to determine axillary vessel involvement. Contraindications to the Tikhoff-Linberg procedure are involvement by the tumor of the neurovascular bundle and of the chest wall, both requiring forequarter amputation. It is important to evaluate the interval between the tumor and vessels very carefully, and this may require surgical exploration prior to resection.

**Figure 126.27.** A: Schematic of the classical Tikhoff-Linberg resection (type IV). This is an extra-articular scapular and proximal humeral resection with the abductors and deltoid removed en bloc. (From Malawer MM, Meller I. A New Surgical Classification System for Shoulder Girdle Resection: Analysis of 38 Patients. Clin Orthop 1981;267:33, with permission.) B: Preoperative angiogram showing a chondrosarcoma (arrows) arising from the superior aspect of the scapula and involving the entire supraspacular area. C: Operative specimen showing the resected scapula and glenohumeral joint covered by muscles in all directions. **Note:** The biopsy site and skin is removed en bloc with the tumor. D: Postoperative radiograph showing a resection of the scapula and glenohumeral joint en bloc. The remaining humerus is suspended to the clavicle by multiple muscle transfers and by the use of dacron tape (Genzyme Surgical Product Company, Fall River, Massachusetts) (see text). E: Clinical photograph following a Tikhoff-Linberg (type IV) resection for a high-grade soft-tissue sarcoma involving the scapula and glenohumeral joint. The extremity is suspended by the use of multiple muscle transfers and Dacron tape from the remaining clavicle. F: A cosmetic shoulder pad in place. The opposite shoulder was used to make a mold.

- Explore the axillary vessels, and if this interval is clear, proceed with the resection. Be prepared to convert from a limb-sparing procedure to a forequarter amputation should tumor involving the neurovascular bundles be encountered. Explore the most medial margin, the paraspinus muscles, and the base of the neck only if there is any possibility of their involvement. It is difficult to evaluate these anatomic areas thoroughly from preoperative studies alone. A forequarter amputation will not improve on this margin.
- Resection includes all of the muscles arising from the scapula and inserting on the proximal humerus and an extra-articular resection of the glenohumeral joint. Occasionally, it is possible to preserve the deltoid muscle and the axillary nerve. Preserve the deltoid muscle whenever possible because it facilitates reconstruction; soft-tissue reconstruction is essential for a good functional outcome—a stable shoulder.
- The neurovascular structures and chest wall must be free of disease. If the tumor extends anteriorly or laterally and involves the rotator cuff or the glenoid, perform a Total scapulectomy (73,77,83,88,94) while preserving most adjacent muscles. Reconstruction involves suspending the scapula from the clavicle by multiple muscle transfers and by the use of dacron tape (Genzyme Surgical Product Co., Fall River, MA) and muscle transfers. Suture the long and short heads of the biceps and coracobrachialis through drill holes to the remaining clavicle, and rotate the pectoralis muscle to cover the defect and to provide stability. Recent reconstructions have used a scapula and proximal humeral replacement.

In general, functional results are the same as those following a Tikhoff-Linberg resection (type IV B) and total scapulectomy (type II A/B): patients retain hand function and good elbow function. The shoulder should be stable and no external orthosis required. A molded shoulder pad improves cosmesis.

Total scapulectomy (73,77,83,88,94) is indicated primarily for low-grade sarcomas (stage I A/B) of the body of the scapula that involve the supraspacular area, low-grade sarcomas of the glenoid, or soft-tissue sarcomas that involve the scapula. Preoperative considerations are similar to those for a Tikhoff-Linberg resection. The neurovascular structures and chest wall must be free of disease. If the tumor extends anteriorly or laterally and involves the rotator cuff or the glenoid, perform an extra-articular resection (type IV B).

- The skin flaps are similar to those obtained from the posterior limb during a Tikhoff-Linberg resection.
- Transect all muscles away from the bone, starting at the lowest point inferiorly. Approach the neurovascular structures from the back, as the scapula is retracted away from the chest in a cephalad direction. Take care to avoid injuring the musculocutaneous and axillary nerves near the coracoid and around the subscapularis muscle.
- Be prepared to convert this approach (type III resection) to a Tikhoff-Linberg resection (type IV B) if the anterior or medial margins are questionable.
- Soft-tissue reconstruction is mandatory to provide stability and to avoid a flail extremity.
- Employ a dual suspension technique using Dacron tape from the clavicle for static support and reattaching the biceps and triceps muscles through drill holes. Tenodesing the deltoid to the pectoralis major and trapezius muscles is essential to provide stability.

The functional results are similar to those with the standard Tikhoff-Linberg resection. This defect occasionally can be reconstructed with a total scapula prosthesis if significant soft tissue remains. The important muscles for this are the latissimus dorsi, rhomboids, and trapezius.

**Scapula and Tikhoff-Linberg Resections**

The surgical exposure, resection, and reconstruction are similar for total scapulectomy (type III) and the Tikhoff-Linberg resections (type IV; interscapulothoracic) (25,75,77). Fig. 126.28 illustrates the technique of a total scapulectomy together with the modifications for performing a Tikhoff-Linberg resection.

**Figure 126.28.** Technique of Tikhoff-Linberg resection (type IV) and a total scapulectomy (type III). A: Make a long, curved incision over the scapula. Develop large fasciocutaneous flaps that permit easy visualization of all muscles attaching to the vertebral and axillary borders. B: Exposure of all three borders of the scapula. The rhomboids and latissimus dorsi muscles are detached. C: Muscle releases. Release all muscles attaching to the scapula. Place your hand between the scapula and chest wall to make sure there is no involvement of the underlying ribs. Then detach the serratus anterior. D: If an intra-articular resection (type III) is to be performed, release the joint capsule (line A). If an extra-articular resection is to be performed, osteotomize the proximal humerus below the capsular attachments (line B).
Gore-Tex reconstruction of the new shoulder capsule (articulated with the polyethylene component of the total scapula. Note the Gore-Tex graft (W. L. Gore & Associates, Flagstaff, Arizona) around the scapula to the of the tumor. This indicates excellent tumor response and a high rate of tumor necrosis. A total scapular and proximal humeral resection in lieu of a forequarter This was a high-grade osteosarcoma prior to induction chemotherapy.

Figure 126.30. High-grade osteosarcoma of the scapula with glenohumeral extension. A: Plain radiograph showing marked destruction and absence of the scapula. This was a high-grade osteosarcoma prior to induction chemotherapy. B: CT scan of the same tumor following induction chemotherapy showing marked reossification of the tumor. This indicates excellent tumor response and a high rate of tumor necrosis. A total scapular and proximal humeral resection in lieu of a forequarter amputation therefore was used to treat this patient. C: Intraoperative photographs following resection and the reconstruction. The proximal humerus is ready to be articulated with the polyethylene component of the total scapula. Note the Gore-Tex graft (W. L. Gore & Associates, Flagstaff, Arizona) around the scapula to the proximal humerus, which acts as a normal capsule maintaining stability and preventing subluxation. D: Intraoperative photograph showing the completion of the Gore-Tex reconstruction of the new shoulder capsule (arrows). The central arrow represents the level of the prosthetic joint. E: Postoperative photograph showing the reconstruction proximally to ensure stability as well as active motion. (b) stabilizing the scapula prosthesis within the humeral component (i.e., creating a new glenohumeral joint), and (c) providing soft-tissue attachments to both the serratus anterior muscle. A partial scapulectomy (75,77) is indicated for low-grade or benign lesions involving only the body of the scapula. It preserves a cuff of infraspinatus, subscapularis, and serratus anterior muscle. Reconstruction consists of suturing these muscles together to close the dead space, and reconstituting the points of origin and insertion of these muscles. A sling is required for 5–7 days. There is minimal functional loss after a partial scapular resection (type II); in fact, shoulder motion and strength are nearly normal. Total scapular resection (type IIIA/B) causes loss of significant shoulder motion, but elbow and hand function are normal; the major limitation is the loss of shoulder abduction. Shoulder-girdle function is similar following total scapular resection and a Tikhoff-Linberg procedure (type V). Soft-tissue reconstruction is the key to establishing shoulder stability. A compressive arm stocking should be worn immediately after surgery to prevent swelling. Encourage the patient to flex the elbow but to avoid extension until there is good wound healing. The patient also needs a sling for 2–4 weeks, by which time the transferred muscles provide a stabilizing force to the entire upper extremity. Forward and back flexion of approximately 30° to 45° is obtained. The goal of rehabilitation is to strengthen the transferred pectorals major, latissimus dorsi, and trapezius muscles around the shoulder as well as the elbow flexors. A shoulder pad contributes to cosmesis and restores symmetry.

Total Scapular and Shoulder Joint Replacement
Experience with total scapular replacement (78), although still limited, is increasing. Generally, if most of the musculature is retained (type IIIA), it is possible to reconstruct the defect with a custom scapular prosthesis (Fig. 126.30). The most common indications for this procedure are large (stage III) giant cell tumors, low-grade chondrosarcomas, and Ewing’s sarcomas following induction chemotherapy. Successful reconstruction poses three primary challenges: (a) replacing the humeral joint, (b) stabilizing the scapula prosthesis within the humeral component (i.e., creating a new glenohumeral joint), and (c) providing soft-tissue attachments to both the scapular and humeral components to ensure stability as well as active motion.
scapular and proximal humeral prosthetic replacement. The polyethylene glenoid cup and Gore-Tex graft are not visualized.

- Reconstruct the glenohumeral joint by sewing an aorta Gore-Tex (W. L. Gore & Associates, Flagstaff, Arizona) graft over the scapula neck and the proximal humerus (Fig. 126.30). This permits stabilization of the joint and provides additional stability.
- Reattach and tenodese the remaining rhomboids, latissimus dorsi, and teres muscle to the prosthesis and to themselves to achieve reliable and functional soft-tissue reconstruction.
- Advance the preserved deltoid proximally and suture it to the trapezius; then close the pectoralis major muscle anteriorly over the new joint.

The function is superior to that of a flail shoulder. Shoulder stability is excellent, and there is good internal, and some external, rotation. If the detiol and portions of the rotator cuff musculature are retained, between 60° and 110° of shoulder abduction can be obtained.

For information about rehabilitation following shoulder procedures, see Rehabilitation Following Shoulder-Girdle Resection in the previous section.

TUMORS OF THE PROXIMAL HUMERUS

Resection and reconstruction of the proximal portion of the humerus is a challenging undertaking (75,77,80,81,86,87). The surgeon should be experienced in shoulder surgery and intimately familiar with the entire anatomy of the shoulder girdle, including the brachial plexus and axillary and brachial vessels, as well as the nerves innervating the shoulder girdle, particularly the musculocutaneous nerve, axillary nerve, radial nerve, and the cords of the plexus. Despite the complexity of these cases, limb-sparing surgery for both high- and low-grade sarcomas of the proximal humerus is possible in approximately 95% of cases (Fig. 126.31). Forequarter amputation is indicated mainly for large fungating tumors, tumors with secondary infections, cases in which there is chest wall involvement, and patients who have had a failed attempt at limb-sparing resection (Fig. 126.32). Preoperative neoadjuvant chemotherapy may allow fracture healing if there is significant tumor necrosis (Fig. 126.33).

Today, limb-sparing surgery is not contraindicated if a pathologic fracture heals during the course of induction chemotherapy. Immobilize the arm during this treatment period. However, approximately 5% to 10% of patients with osteosarcomas cannot be treated by a limb-sparing resection because of their extremely large size or because of vascular or neurologic involvement, infection, or pathologic fracture that does not respond to treat- ment.

Stage I (low-grade) sarcoma of the proximal humerus can be treated by type I excision with minimal functional deficit. High-grade sarcomas require a modified Tikhoff-Linberg resection (type V). Intra-articular and synovial involvement is more common with high-grade chondrosarcomas and osteosarcomas of the shoulder girdle than at other anatomic sites. Thus, extra-articular, rather than intra-articular, resections are recommended for high-grade tumors of the proximal humerus. Take care not to contaminate the anterior structures when performing a biopsy. Prosthesis, allograft, or dual fibula autograft can be used for reconstruction following a marginal resection (type I) for a low-grade lesion. Following resection of a high-grade lesion (stage IIB), the aim is a stable shoulder with minimal motion to preserve function in the elbow and hand. Regardless of the type of reconstruction, the magnitude of the surgical resection depends on the grade of the tumor and its anatomic...
extent. Specific anatomic and surgical considerations are summarized next.

Tumors of the proximal humerus often grow large and present with an extrasosseous component, particularly with most high-grade osteosarcomas, chondrosarcomas, and Ewing’s sarcomas. The relatively small size of the glenohumeral joint in comparison to the knee or hip joint almost always mandates an extra-articular resection to obtain negative margins. The recommendation is to treat most stage III bone sarcomas by an extra-articular resection. Usually, this requires a resection of the deltoid muscle as well as the axillary nerve. Any attempt to preserve either structure is risky and not recommended unless there has been a very good response to induction chemotherapy.

Arterial involvement rarely occurs, but often there is displacement of the vessel. The subcapsularis muscle protects the brachial vessels and major nerves. The relationship of the axillary vessels and the brachial vessels must be evaluated preoperatively and routinely explored, and these vessels must be dissected free during the initial surgical exposure prior to the resection. Occasionally the brachial veins or axillary veins may be the site of mural (tumor) thrombi. Significant arm swelling and edema are important signs of vascular compression or involvement, or tumor thrombosis.

The musculocutaneous nerve, which travels between the brachialis and biceps muscles, is rarely involved unless the tumor extends to the conoid. To avoid damage, it is imperative to identify this nerve before exploring the brachial vessels and mobilizing the arm muscles. Similarly, the tumor rarely involves the radial nerve, which arises from the posterior cord and passes posterior to the humerus at the inferior border of the latissimus dorsi muscle. However, the radial nerve is often displaced and can be easily damaged. It is also necessary to identify it before performing a hemeral osteotomy.

A major consideration in the preoperative evaluation and surgical planning is the intraosseous extension of the tumor within the bone marrow. The humerus is shorter than the femur andibia, the two most common sites of sarcomas, and large tumors of the humerus often require resection of a significant portion of the bone. It is not unusual to resect 50% to 80% of the humerus. Tumors arising within the depth of the tumor require a subtotal humeral resection and replacement of the glenohumeral and elbow joints. Be prepared with various lengths and diameters of intramedullary staples. Base the final decision of bone length on the frozen section of the osteotomized humerus at the time of resection.

The abductor mechanism, that is, the deltoid muscle and the rotator cuff, normally cover the shoulder joint. With high-grade proximal humeral sarcomas, these structures are usually resected. Following the resection, joint cover and stability are essential to eliminate dead space, decrease the risk of infection, and maintain good elbow and hand function. The key muscle transfers in the reconstruction are the pectoralis major muscle and the latissimus dorsi muscle; these must be identified and preserved during the resection.

PREOPERATIVE IMAGING STUDIES

Magnetic resonance imaging and bone scan studies accurately demonstrate the soft-tissue extension as well as the intraosseous extent of the tumor (75,77,80,81). Pay careful attention to the level of marrow extension and thus the level of humeral resection, as well as to the extent of tumor along the shoulder joint, rotator cuff, and axillary space. Evaluate the scapula for transarticular skip metastases. Also evaluate the possibility of tumor extension along the subcapsularis and the other rotator cuff muscles; if it is present, a wider resection is required.

A CT scan complements the MRI and bone scan by providing the best demonstration of bony disease and cortical involvement. At this point, evaluate the chest wall, axilla, and ribs for tumor involvement.

Angiography is required prior to resection to evaluate the brachial and circumflex vessels, which are often displaced. A decrease of tumor blush correlates with the tumor response to induction chemotherapy. A minimal tumor blush indicates a high degree of tumor necrosis, which may permit less tissue to be resected and may alter the necessary margins. The venous flow phase is useful to demonstrate venous occlusion or tumor thrombi. If there is any suggestion of occlusion, perform a brachial venogram.

BIOPSY TECHNIQUE

As always, it is essential to plan and perform the biopsy carefully because an inappropriate biopsy is a common cause of forequarter amputation (Fig. 126.27). In a patient with a surgically involved humerus, a core needle biopsy through the anterior third of the deltoid muscle is recommended (75,77,80). Open biopsies are rarely required and may lead to excessive local contamination. If there is a soft-tissue component, which occurs 95% of the time, there is no need to enter the bone. It is possible to perform multiple biopsies through one puncture site to obtain adequate material. Take care to avoid the deltoidopectoral groove. Contamination of this groove leads to contamination of the pectoralis muscle and potentially of the brachial vessels and axillary space. The axillary nerve innervates the deltoid muscle posteriorly, so the muscle can be partially resected without any loss of function if the muscle is to be preserved.

MANAGEMENT OF SPECIFIC TUMORS OF THE PROXIMAL HUMERUS

Specific tumors of the proximal humerus demand special treatment. The proximal humerus is the third most common site for osteosarcoma. Osteosarcomas in this area tend to have a poorer prognosis than those around the knee, and most have a significant extrasosseous component. Plain radiographs suggest the correct diagnosis. Perform all staging studies prior to biopsy. If the axillary vessels are free of tumor, a limb-sparing procedure is generally indicated—preferably an extra-articular resection (type IB). A modified Tihoff-Linberg procedure (type V) provides adequate resection of the proximal humerus for high-grade bone sarcomas. This includes en bloc removal of 15-20 cm of the humerus and shoulder joint, with the deltoid, rotator cuff, and portions of the biceps and triceps muscles.

Reconstruction involves suspension of the arm, motor reconstruction, and provision of adequate soft-tissue coverage.

Primary (central) and secondary (peripheral) chondrosarcomas commonly occur in the proximal humerus. The peripheral lesions tend to be large but low grade, whereas the central lesions tend to be a higher grade. Stage I tumors of the proximal humerus can be treated by excision (type I) with minimal functional deficit. High-grade sarcomas require a modified Tihoff-Linberg resection (type V) or, rarely, a forequarter amputation. Intra-articular and synovial involvement with high-grade cartilaginous lesions are more common in this location than in other sites. Take care not to contaminate the anterior structures when performing the biopsy. An allograft prosthesis accomplishes the reconstruction following a marginal resection (type I) for a low-grade sarcoma.

Although this is the third most common site for osteosarcomas, fewer than 10% of Ewing’s sarcomas involve the proximal humerus. The flat bones, specifically the clavicle and scapula, are the most common sites for Ewing’s sarcomas. The treatment follows the guidelines for other high-grade bone sarcomas of the humerus. Surgery should never precede induction chemotherapy. Evaluate by CT scan, MRI, bone scan, and angiography when deciding whether to perform a limb-sparing resection. If a round cell tumor is suspected, first perform a small core biopsy. Because the patient may receive radiation therapy, it is important not to make a large hole in the underlying bone that might not heal. As previously mentioned, resection of Ewing’s sarcoma is increasingly replacing radiation therapy. Ewing’s sarcomas, unlike osteosarcomas, may dramatically decrease in size following induction chemotherapy, in which case the deltoid and axillary nerve may be preserved. For this reason, intra-articular resections are recommended. However, do not use radiation therapy in patients treated with a prosthesis or an allograft because it often leads to several local complications, such as restriction of motion, infection, and secondary amputation.

All carcinomas can metastasize to the proximal humerus. In specific situations, large metastatic tumors with marked bony destruction may be resected by a primary resection and prosthetic replacement. Hypernephroma, which is extremely vascular and has a predilection to this location, may present a unique problem of uncontrollable bleeding. Radiography often reveals marked destruction and ballooning, much like an aneurysmal bone cyst or primary sarcoma. Simple biopsy, even with a needle, may lead to severe hemorrhage. Preoperative angiography with embolization is recommended. Ligate the anterior and posterior circumflex vessels prior to any surgical procedure. If curettage and cementation are not feasible, a resection and prosthetic replacement (type I) is indicated.

RECONSTRUCTION FOR TUMORS OF THE PROXIMAL HUMERUS

Endoprosthetic replacement for reconstruction of the proximal humerus (75,77,80,81), which has been in use since 1973, is the most common technique for reconstructing large proximal humeral defects. It may be used for both intra-articular and extra-articular defects (i.e., when retaining the glenoid as well as when resecting it with the tumor specimen) (Fig. 126.34).
Types of prostheses utilized for replacement and reconstruction of the proximal humerus. A: The initial vitallium prosthesis used in the 1940s. B: A long-stem Neer prosthesis (Howmedica, Rutherford, NJ) first used by Dr. Ralph Marcove at Memorial Sloan-Kettering Cancer Center during the 1960s. C: A proximal humeral modular replacement prosthesis (the MRS) developed by Howmedica (Rutherford, NJ) in 1988. This design is popular today.

Originally, each patient received a custom-made prosthesis. In 1988, Howmedica (Rutherford, NJ) developed the Modular Replacement System (MRS), which has since undergone several technological improvements. The present system is shown in Figure 126.35. Modular prosthetic systems are now widely available (from Howmedica; Biomet, Warsaw, IN; and Sulzermedical, Austin, TX) and obviate the need for custom devices. These prostheses have proven to be very durable. The reported rates of fracture, infection, nonunion, tumor recurrence, reoperation, and time of immobilization are all lower following endoprosthetic replacement than with allografts or composite reconstruction. Low-grade tumors are treated by an intra-articular resection and preservation of the abductor mechanism.

An MRS is used for both intra- and extra-articular reconstructions. The reconstruction is combined with multiple muscle transfers to reconstruct the soft tissues that have been resected. For high-grade bone sarcomas, this is the method of choice. The deltoid and axillary nerves are routinely removed along with the glenohumeral joint. High-grade tumors often cross the glenohumeral joint and are a source of local tumor recurrence; therefore, intra-articular resections and reconstructions with osteoarticular allografts are not recommended. Treat low-grade tumors with an intra-articular resection and preservation of the abductor mechanism.

Soft-tissue reconstruction is essential to cover the prosthesis and create shoulder stability in a patient who has undergone resection of the proximal humerus (Fig. 126.36). This is accomplished through a technique of dual suspension that entails static and dynamic reconstruction. Use Dacron tape to secure the prosthesis horizontally, and secure the Dacron tape by drill holes in the remaining bony structures (i.e., clavicle and scapula or clavicle alone). The two sets of Dacron tape provide mediolateral and craniocaudal stability. Dynamic suspension, provided by transfer of the short head of the biceps muscle to the stump of the clavicle, allows elbow flexion.

Preservation and transfer of the pectoralis major, trapezius, supraspinatus, infraspinatus, teres minor, teres major, and latissimus muscles provide mobility of the shoulder. These muscle groups offer dynamic support, assist in suspension of the prosthesis, and provide soft-tissue coverage, which is essential in preventing skin problems and secondary infection.

Endoprosthetic replacement is highly predictable and successful. There are minimal problems with subluxation following adequate soft-tissue reconstruction. Malawer et al. (75,76,80,81), who have the most extensive experience with replacing the proximal humerus with the MRS, report 95% survival of the prosthesis as determined by Kaplan-Meier analysis at 10 years (Fig. 126.37). Type I resections are routinely reconstructed with the prosthesis and the soft-tissue transfers described; extra-articular resections are reconstructed with the proximal humeral prosthesis lying anterior to the scapula. A Gore-Tex graft reconstruction of the joint may provide stability following a type I resection, even when normal soft tissues are retained. The most common problem is temporary nerve palsy, which occurs in approximately 10% of patients, usually involving the radial nerve and musculocutaneous nerves. Infections and skin flap necrosis occur rarely (1% to 2%) after endoprosthetic replacement around the shoulder.
Osteoarticular (allograft) replacements were widely used for segmental joint replacements in the 1960s and 1970s, but they have become less popular in the past two decades. The rate of complications, which include infections, fracture through an allograft, nonunions, pain, and instability, is significantly higher than with endoprosthetic replacements for stage IIB bone sarcomas. Today, there are few indications for the use of either osteoarticular or composite allograft. The most common indications are for low-grade or aggressive benign bone tumors when most of the adjacent soft tissue can be preserved. Osteoarticular replacement is not indicated following high-grade tumor resection because of the need to retain the rotator cuff, deltoid, and axillary nerve, and the corresponding high rate of recurrence.

In 1991, among 20 cases of osteoarticular allografts out of 450 allografts performed at Massachusetts General Hospital, there were seven fractures, three infections, and one nonunion (83). Three of the allografts had to be removed and replaced, and flexion was seldom above 45°. Most of the allografts were for low-grade sarcomas or benign tumors (e.g., giant cell tumors). Two of the three stage IIB osteosarcomas recurred locally and required amputation. Only seven patients had no complications. We do not recommend osteoarticular allografts for stage IIB sarcomas (i.e., high-grade tumors with extra-articular components). One can generalize these concerns to composite allografts.

**OPERATIVE TECHNIQUES**

**Osteoarticular Allograft**

- For an osteoarticular allograft for the proximal humerus, carefully size the allograft preoperatively.
- When performing the procedure (Fig. 126.38), place the allograft into the patient and fix it with a cortical plate, intramedullary rod, or both. Cement the intramedullary fixation into the allograft and impact it into the remaining humerus before affixing the plate. The technique of intramedullary fixation with a small derotation plate decreases the rate of fracture and nonunions. To avoid subluxation and pain, it is essential to perform the soft-tissue reconstruction of the joint and capsule tightly.
- Suture the subscapularis and rotator cuff to the corresponding soft-tissue components on the allograft.

![Figure 126.38](image)

**Notes on Allograft Technique**

Composite allografts have been developed to decrease the complications of an osteoarticular replacement. The technique of combining a prosthesis with an allograft is to provide a stable joint surface and to avoid articular collapse, which is extremely common following osteoarticular replacement alone. This entails cementing a long-stem humeral prosthesis [Neer type (Howmedica, Rutherford, NJ)] into the allograft and fixating it into the remaining humerus. Although it is still popular, it offers no advantage over endoprosthetic replacements and has higher infection and complication rates (e.g., nonunions and instability). The main indications for allograft reconstructions are low-grade tumors in which the deltotoid and rotator cuff musculature can be retained and adjuvant chemotherapy is not required.

The surgical technique of reconstruction for composite allograft is similar to that of noncomposite allograft replacements. The main difference is the use of a long or short endoprosthetic proximal humeral component (Neer type) to replace the humeral head. This is done to avoid subchondral fractures, which have been reported with allografts alone. The fixation of the long stem into the remaining bone appears to decrease the nonunion rate. Usually, plate fixation is added, although this remains an issue of debate. The soft-tissue reconstruction following composite allograft fixation is identical to that of osteoarticular replacements.

There have been several attempts to develop an intercalary arthrodesis using an allograft fixed to the remaining distal humerus and scapula or glenoid. This is an extremely difficult, time-consuming procedure. Complications are numerous and include nonunion, skin necrosis, and metal or plate breakage. In addition, many patients who have undergone arthrodesis complain about the lack of rotation, which other reconstructive techniques preserve. In general, the maximal abduction is only 30° to 45°. We do not recommend arthrodesis.

The oldest surgical technique is resection leaving a flail shoulder. Before endoprosthetic and allograft reconstruction, the shoulder girdle was left unreconstructed after resection. The patient needed a large, bulky, external orthosis to support the upper extremity and prevent the arm from pulling on the brachial plexus and vascular structures. This approach does not permit any type of stability and, moreover, it does not afford a stable fulcrum, which is necessary for elbow function. This procedure is recommended only following failed reconstruction, usually in patients with infections that cannot be resolved.

One technique that is no longer used is arthrodesis with dual fibular strut grafts (Fig. 126.39). The original procedure, described using autogenous fibula bone grafts in the 1970s (before modern endoprosthetic and composite allograft reconstruction), was to remove both fibulas from the patient, screw them together proximally to form a pseudohumeral head, and then fix this to the adjoining host bone. It is a reliable method of reconstruction, but it has an extremely high morbidity and is not in common use now.
During the 1980s, the development of microvascular anastomosis techniques in free tissue and bone transplants permitted surgeons for the first time to transplant a single fibula with its attached blood supply to reconstruct the proximal humerus. This technique, which involves the end-to-side anastomosis of the peroneal artery (supplying the fibula) to the brachial artery, is extremely time-consuming, and there is minimal evidence that the fibular transplants remain viable. Bone scans and angiography have been used to show postoperative patency of the vascular anastomosis. Single fibulas, even when vascularized, have high incidences of stress fractures, subluxation, and dislocation. This technique has recently been combined with osteoarticular allograft arthrodesis to reinforce the allograft and promote its incorporation in the glenoid and scapula and the remaining humeral bone. It has not been demonstrated that this technique has a higher incorporation rate than nonvascularized fibula transplants to humeral defects. Although appealing, it has not been widely used.

**Extra-articular Proximal Humeral Resection and Prosthetic Reconstruction**

The technique of extra-articular proximal humeral resection and prosthetic reconstruction (Fig. 126.40) permits modification for an intra-articular resection (75,77,80). We recommend an extra-articular (type V) resection. This method may be modified if an intra-articular resection is to be performed for low-grade sarcomas. The method of soft-tissue reconstruction and prothetic suspension was described previously. In general, the deltoid muscle and axillary nerve cannot be preserved for high-grade sarcomas. Three osteotomies are required for an extra-articular resection.

**Fig. 126.39.** Dual fibular arthrodesis of the humerus to the scapula following proximal humeral resection.

**Fig. 126.40.** Surgical technique of resection of the proximal humerus for high-grade bone sarcomas. (From Sugarbaker PH, Malawer MM. *Musculoskeletal Surgery for Cancer: Principles and Techniques.* New York: Thieme Medical, 1992; Chapter 27, with permission.) A: Make an anterior incision to permit wide exposure of the axilla, axillary and brachial vessels, shoulder joint, and anterior scapula. B: The key to the exposure of the axilla and its contents is the release of the pectoralis major muscle and the short head of the biceps and pectoral minor from the coracoid. C: Expose the anterior neck of the scapula. Transect the subscapularis muscle. The capsule attaches lateral to the coracoid. Make the scapula osteotomy (dotted line) lateral to the coracoid so as not to enter the joint. Perform this osteotomy after the posterior exposure. D: Posterior incision. The anterior incision is now a T to permit exposure of the posterior aspect of the shoulder musculature and to allow the scapular osteotomy to be performed safely. If an intra-articular resection is performed, steps (D) and (E) are omitted. E: Palpate the glenoid and transect the covering muscles. This permits direct exposure of the posterior scapula and glenoid neck. F: Reconstruction with a modular prosthesis. G: Major muscle reconstructions.

- Place the patient in a lateral position, allowing some mobility of the upper torso.
- Prepare the skin down to the level of the midline anterior and posterior to the umbilicus, and cranially past the hairline.
- Start the incision over the junction of the inner and middle thirds of the clavicle, continue along the deltopectoral groove, and then move down the arm over the medial border of the biceps muscle (Fig. 126.40A).
- Excise the biopsy site, leaving a 2–3 cm margin of normal skin. Do not open the posterior incision until the anterior dissection is complete.
- For exploration of the axilla, open the skin through the superficial fascia.
- Dissect the skin flap anteriorly from the pectoralis major muscle to expose its distal third, and uncover the short head of the biceps muscle. The key to exposure of the anterior shoulder girdle and axilla is the detachment and mobilization of the pectoralis major muscle with partial mobilization medially toward the chest wall (Fig. 126.40B).
- Dissect the pectoralis major muscle overlying the axilla free of fat, so that its insertion on the humerus can be visualized. Then divide this muscle just proximal to its tendinous insertion on the humerus, and use a suture to tag the portion of muscle remaining with the patient.
- Identify the axillary sheath and visualize the coracoid process. To expose the axillary sheath along its full extent, divide the pectoralis minor, short head of the biceps, and coracobrachialis muscles at their insertion on the coracoid process. Tag all proximal muscles with a suture for later identification and use in reconstruction.
- Before exploring the neurovascular bundle, develop the skin flaps just minimally. If the patient’s tumor is found unsuitable for limb-salvage surgery, more extensive flap dissection would lead to tumor contamination of the skin needed for forequarter amputation.
- In dissecting the neurovascular bundle, pass vessel loops around the neurovascular bundle near the proximal and distal ends of the dissection. Medial traction on the neurovascular bundle allows visualization of the axillary nerve, posterior circumflex humeral artery, and anterior circumflex humeral artery. (It is rare to preserve the axillary nerve in large stage IIIb sarcomas of the proximal humerus, but if the tumor is small and intraosseous, the nerve can be preserved.) Ligate these three structures and divide them.
- If the neurovascular bundle is tumor free, proceed with dissection for a limb salvage procedure.
- Isolate and preserve the musculocutaneous nerve, although it is occasionally necessary to sacrifice this nerve to preserve tumor-free margins of resection.
- Divide the deep fascia between the short and long heads of the biceps muscle; this permits easy visualization of the musculocutaneous nerve.
- Identify the radial nerve at the lower border of the latissimus dorsi muscle, where it passes around and behind the humerus in its midportion (spiral groove) into the triceps muscle group.
- Pass a finger around the humerus to bluntly move the nerve away from the bone.
- Trace the ulnar nerve down the arm; you must divide the intermuscular septum between the biceps and the triceps over the nerve to see it clearly.
- It is necessary to divide the muscle groups anteriorly to expose the neck of the scapula if performing an extra-articular resection (Fig. 126.40C). Separate the short and long heads of the biceps to expose the humerus. Determine the site for the humeral osteotomy, and transect the long head of the biceps and brachialis muscles at this level.
- Identify the inferior border of the latissimus dorsi muscle, and make a fascial incision that makes it possible to pass a finger behind the latissimus dorsi and teres major muscles several centimeters from their insertion.
- Transect the latissimus dorsi and teres major muscles using electrocautery.
- External rotation of the humerus exposes the subscapularis muscle, which is transected at the level of the coracoid process. Take care not to enter the joint space. Tag the portions of these muscles that will remain with the patient for future reconstruction. Transecting these muscles exposes the anterior portion of the neck of the scapula.
- Now move to the posterior aspect of the patient. Rotate the table, if desired, to provide better visualization.
- Begin the posterior incision anteriorly over the junction of the middle and lateral thirds of the clavicle and continue down over the lateral third of the scapula past the lower edge of this bone.
- Develop a skin flap by dissecting the skin and subcutaneous tissue between the anterior and posterior incision from the underlying deltoid muscle down to the level of the midhumerus.
If removing the entire scapula (type VI resection), make the posterior incision longer and curve it posteriorly to allow the skin flap to expose muscle over the entire scapula.

Next, divide the posterior muscle group (Fig. 126.40D). Divide the thick fascia that joins the posterior border of the deltidoid muscle to the infraspinatus muscle and scapular spine. Leave the deltidoid muscle intact to cover the tumor mass.

Transsect the trapezius muscle from its insertions on the scapular spine and acromion.

Pass your index finger beneath the teres minor up to the area of the planned scapular osteotomy. Transect the supraspinatus, infraspinatus, and teres minor muscles over the neck of the scapula, thus allowing the plane of transection through the neck of the scapula to be exposed. Tag all transected muscles proximally (Fig. 126.40E).

While shielding the radial and ulnar nerves, transect the triceps muscles at the level selected.

Perform circular, clavicular, and humeral osteotomies as follows. Divide the clavicle at the junction of its middle and inner thirds. This is usually accomplished with a Gigli saw.

Divide the scapula through its surgical neck medial to the coracoid process, also using a Gigli saw.

Remove the entire specimen, taking care to protect all the neurovascular structures at each osteotomy site.

If resecting the entire scapula, take the skin flap back to the medial edge of the scapula.

Divide the rhomboid, levator scapula, and trapezius muscles from their insertions on the scapula. It is unnecessary to divide the teres major, teres minor, supraspinatus, infraspinatus, and subscapularis muscles when performing a full scapular resection.

Transsect the humerus 4–6 cm distal to the tumor, as determined by preoperative bone scan.

Obtain frozen sections of tumor margins and touch preparations for cytologic examination of the margin at the site of the osteotomy.

Measure the section of humerus removed and select a prosthesis 1–2 cm shorter. Some shortening of the extremity facilitates soft-tissue coverage and closure.

Reconstruct the defect with a modular prosthesis (Fig. 126.40F). The head of the prosthesis sits anterior to the remaining scapula, which has a normal concavity.

Place the head in 30° to 45° of retroversion.

The soft-tissue reconstruction consists of static and dynamic supports. Use dacron tapes (static) to suspend the prosthesis from the remaining scapula as well as from the clavicle.

The major muscle reconstructions (Fig. 126.40G) are the pectoralis major to the lateral border of the scapula, thus covering and supporting the prosthesis. The reaming muscles, the trapezius, supraspinatus, infraspinatus, and latissimus dorsi are tenodesed to the transferred pectoralis muscle.

The final closure is to tenodese the biceps and triceps to each other and to the pectoralis proximally. This establishes a very stable shoulder girdle.

Reconstruction

Once the specimen has been removed, a generous amount of soft tissue should still cover the tumor. The long and lateral heads of the biceps muscle remain on the humerus. The upper portion of the long head of the biceps and the upper portion of the brachialis muscle remain with the specimen. The entire deltidoid muscle covers the tumor. The insertions of the supraspinatus, infraspinatus, pectoralis major, latissimus dorsi, teres major, teres minor, and subscapularis muscles remain covering the tumor and constitute the free margins.

Total Humeral Resection

Total humeral resection as shown in Figure 126.41 (i.e., removal of the shoulder and elbow joints) and replacement is an unusual procedure (75). It is indicated when the tumor involves a large component of the medullary shaft. In such cases, an endoprosthesis or allograft would not be successful because only a short distal segment remains following resection. A second and more common indication for total humeral resection is Ewing’s sarcoma of the humeral diaphysis. Induction chemotherapy will often shrink the large extraosseous component frequently associated with Ewing’s sarcomas, making a resection possible.

![Figure 126.41](image)

Plain radiograph of a total humeral prosthesis following resection of the entire humerus, glenohumeral joint, and elbow joint for a large diaphyseal osteosarcoma that extended both proximally and distally.

Anatomic considerations relative to the proximal humeral component are similar to those previously described. Considerations relating to the midshaft and distal humerus center on the relationship of the tumor to the brachial artery and nerves. Angiography is required to determine the relationship to the brachial vessels medially and the antebrachial fossa. Use MRI and bone scan to determine the extent of the humeral involvement, which determines whether total humeral resection is required.

Remove the entire humerus in patients who have round cell tumors of the humerus and diaphysis.

- The surgical approach is similar to that of a type V resection using multiple muscle transfers and dacron tape (Fig. 126.42).

![Figure 126.42](image)

Technique of total humeral resection and replacement. A: Continue the anterior incision to the elbow and across the joint to permit exposure to the brachial vessels, and the median, ulnar, and radial nerves, which all must be identified and retracted. B: A modular distal humeral body—a component of the MHS. Insert the olecranon component anteriorly. Attach the flexors and extensors to suture holes in the prosthesis with dacron tape (Genzyme Surgical Product Company, Fall River, Massachusetts). Then repair the biceps to adjacent soft tissues.

- Explore the vessels proximally, release the circumflex vessels proximally, and identify the musculocutaneous, axillary, and radial nerves.

- In addition, mobilize the brachial vessels throughout the length of the arm into the antebrachial space to protect them and the accompanying medial nerve. The ulnar nerve passes posteriorly through the intramuscular septum and can easily be identified in the mid arm.

- Likewise, identify the radial nerve as it passes around the humerus and into the interval between the biceps and brachioradialis muscle, where it becomes the posterior interosseous nerve. It is necessary to identify and to initially preserve all of these nerves, as well as the brachial artery and vein (Fig. 126.42A).

- The resection is similar to that of the proximal humerus lesions, but continue it down to the elbow joint, which is opened anteriorly after mobilizing the brachial vessels and the median nerve through the antebrachial fossa. Avoid a posterior approach to the elbow. Keep the triceps tendon attached to the olecranon.

- Open the capsule of the elbow joint circumferentially; this makes it possible to fit the elbow component and seat it into the olecranon. Detach the flexor and extensor muscles from their respective origins on the humeral condyles. Retract the biceps, but do not detach it from its insertion onto the radial tuberosity.

- Use one of the several elbow devices available (Fig. 126.42B). An intramedullary stem fixed with polymethylmethacrylate (PMMA) is widely used.

- Soft-tissue reconstruction of the elbow consists of reattaching the forearm flexor and extensor muscles to holes in the prosthesis.

- The ulnar nerve is routinely transposed anteriorly to avoid irritation from the prosthesis. Then repair the biceps to the adjacent soft tissue.

- Measure the section of humerus removed and select a prosthesis 1–2 cm shorter. Some shortening of the extremity facilitates soft-tissue coverage and closure.

- Reattach the elbow flexors and extensors with polyethylene tendon grafts (Fig. 126.43). A modular distal humeral body—a component of the MHS. Insert the olecranon component anteriorly. Attach the flexors and extensors to suture holes in the prosthesis with dacron tape (Genzyme Surgical Product Company, Fall River, Massachusetts). Then repair the biceps to adjacent soft tissues.
Finally, a basic understanding of the urogenital anatomy is important in dealing with pelvic lesions with significant intrapelvic masses. In the retroperitoneum, the ureter cause a significant vascular problem. Thus, vascular involvement itself is rarely a contraindication to limb salvage; the external iliac system can be bypassed, and the anastomosis around the hip with terminal branches from the internal iliac system. Within the pelvis, the internal iliac vessels lie posterior to the external iliac vessels as is the main pedicle to the lower portion of the rectus abdominus muscle, which can be used as a rotational flap for soft-tissue coverage. Once the artery passes under gives rise to the deep circumflex iliac and inferior epigastric arteries. The inferior epigastric artery is important in terms of potential soft-tissue reconstruction because it greater latitude of nerve displacement possible. In many cases, although the nerve is displaced, it still can be preserved. This is certainly in contrast to the tight femur may also have soft-tissue extensions near the sciatic nerve. Fortunately, the farther the nerve gets from the sciatic notch, the more mobile it becomes, making a functionless and insensate, and it also sacrifices the neurologic function to all of the gluteal muscles. Lesions involving the lower portion of the ischium or proximal soft-tissue extension either extrapelvically or intrapelvically near the sciatic notch usually require sacrifice of the entire sciatic nerve. This renders the lower leg masses in this area. It is most tightly confined where it passes beneath the inguinal ligament and over the pubis near the iliopectineal eminence. Large lesions in this area may require sacrifice of the nerve roots exiting the L-2, L-3, and L-4 levels. It courses along the lateral side wall of the pelvis, just over the pelvic brim, and exits the pelvis through the obturator foramen. It can also easily be involved with periacetabular lesions or pubic lesions and may require sacrifice. This certainly denervates the adductor muscles of the thigh, but it does not significantly compromise gait. Its preservation, therefore, is not a requirement for limb salvage.

The vascular anatomy of the pelvis is complex, but it can be simplified for the purposes of limb salvage to that of an anterior, or external, iliac artery distribution and a posterior, or internal iliac artery distribution. The external system has no significant branches within the pelvis until it gets to the level of the internal iliac. There it gives rise to the deep circumflex iliac and inferior epigastric arteries. The inferior epigastric artery is important in terms of potential soft-tissue reconstruction because it is the main pedicle to the lower portion of the rectus abdominus muscle, which can be used as a rotational flap for soft-tissue coverage. Once the artery passes under the inguinal ligament, it becomes the common femoral artery and eventually the superficial and profunda portion. The medial and lateral femoral circumflex arteries generally arise and run the profunda branch. They not only provide much of the blood supply to the proximal portion of the femur, but they also contribute to the rich Anastomosis around the hip with terminal branches from the internal iliac system. Within the pelvis, the internal iliac vessels lie posterior to the external iliac vessels as they travel toward the sciatic notch. They become tightly adherent to the pelvic side wall as they course over the sacrum and pelvic brim and begin to divide into multiple terminal branches: superior and inferior gluteal, internal pudendal, and obturator, as well as branches providing blood supply to the intrapelvic contents such as the bladder and, in the female, the uterus. Tumors of the pelvis, with soft-tissue extensions inferior to the pelvic brim, can often involve these vessels or significantly distort the arterial arc of the internal iliac system, often necessitating a systemic approach to conservative pelvic resection. This itself does not cause a significant vascular problem. Thus, vascular involvement itself is rarely a contraindication to limb salvage; the external iliac system can be bypassed, and the internal iliac system is unnecessary.

Finally, a basic understanding of the urogenital anatomy is important in dealing with pelvic lesions with significant intrapelvic masses. In the retroperitoneum, the ureter is ruptured and the prosthesis will fall into the retroperitoneal space around the urogenital tract. Elevation is required for the first 72 hours. Rehabilitation must focus on both the bladder and the elbow joints. Fortunately, it is possible to preserve most of the musculature of the shoulder girdle, which allows for an extremely stable shoulder girdle as well as preservation of most of the elbow musculature.

**TUMORS OF THE HIP AND PELVIS**

Anatomical complexity and reconstructive challenges of limb salvage make the hip and pelvis one of the most difficult areas of musculoskeletal oncology surgery. Prior to the development of limb-salvage techniques for pelvic tumors, the best patients could only be salvaged with resection of multiple abdominal viscera or hemipelvectomy. The resulting emotional and functional impact for these patients, however, was considerable. Even as limb-salvage techniques developed for other anatomic areas, management of pelvic lesions was still fraught with higher complication rates and less satisfactory functional results (52, 53, 125, 127). The renal mass effect and the pelvic mass effect that characterized pelvic tumors were often no better tolerated than the retroperitoneal mass effect, and the impetus to extend the indications for limb salvage to include even large pelvic lesions, provided some sort of functioning extremity could be preserved. Anatomical approaches and reconstructive techniques eventually became more standardized, and a limb-salvage approach for many pelvic lesions developed. Furthermore, the development of computed tomography and magnetic resonance imaging allowed better comparison of functional results achieved with conservative limb salvage techniques (50). With more recent improvements in spinal fixation techniques, reconstruction for lesions involving the sacrococcygeal area and even some lesions requiring resection of the portion of the spine are possible in selected patients.

**ANATOMIC CONSIDERATIONS**

An understanding of the complexity of pelvic anatomy, and to a lesser degree proximal femoral anatomy, is key to successful limb salvage. The bony pelvis forms a complete ring, with the two hemipelvis adjoined anteriorly at the symphysis pubis and posteriorly by the sacrococcygeal (SI) joints. Although portions of the SI joints are true diarthrodial joints, the close proximity of the ilium to the sacrum, as well as dense ligamentous attachments, distinguish them from other large synovial joints. This has important implications in tumor surgery because these joints, and for that matter the symphysis pubis, do not present the same relative barrier to tumor spread as do other joints. Extensions of tumor across the SI joints are not uncommon, with large masses of tumor from the ilium frequently extending across the SI joint anteriorly in the sacrum.

Each hemipelvis comprises the ilium, ischium, and pubis, with each of these bones contributing to the acetabulum. Because these bones fuse at skeletal maturity, resections of the pelvis tend to be classified not simply according to the bone that is removed, but rather by the zone of the pelvis involved.

The large iliac wing serves primarily as a site of muscle attachment, along both the iliac crest and the iliac and gluteal fascias. Tumors arising within the ilium, even with soft-tissue extension, are almost completely surrounded by muscle, which can aid in developing surgical margins. The ilium is not simply a site of muscle attachments, however. The posterior medial portion from the pelvic brim to the sciatic notch is very thick and forms the structural continuity between the acetabulum and the sacrum. Removal of the iliac wing that can preserve even a part of this portion of the ilium will leave a structurally intact pelvic ring and often require no significant reconstruction.

The ilium contributes a large part of the posterior portion of the acetabulum, as well as a portion of the structural posterior column of the pelvis. It has important ligamentous and osseous attachments as well as the iliacus and obturator internus muscles. The ilium and acetabulum form a significant part of the bony pelvis. At the superior border of the ilium, the iliac crest provides the main pedicle to the lower portion of the rectus abdominus muscle, which can be used as a rotational flap for soft-tissue coverage. Once the artery passes under the iliacus and obturator internus muscles, and serves to define the greater and lesser sciatic notches. Muscle attachments such as the coccygeus, levator ani, and obturator internus help form the floor of the true pelvis. Furthermore, the ischial tuberosity serves as the origin for the hamstrings. Not only the ischium’s important bony function, but also the important soft-tissue attachments and proximity of other important neurovascular structures make tumors arising within the ilium difficult to manage.

The pubis is the smallest of the three pelvic bones and, in some ways, the most expendable. It contributes to a part of the anterior aspect of the acetabulum, but a structure that is not essential to bony integrity. At the superior pubic ramus, the iliopectineal eminence forms a prominent anterior projection inferior to the inguinal ligament and superior to the pubic tubercle. The iliopectineal eminence is a key landmark for determining the extent of pelvic resection.

Lesions of the pelvis, particularly if any soft-tissue mass exists, can often be intimately associated with these structures, making preservation sometimes difficult.

Although an understanding of the bony pelvis is important in determining levels of resection and structural continuity of the limb, it is the soft-tissue anatomy, in terms of muscle and soft-tissue structures, that most significantly contributes to the ultimate function of the limb. Of primary importance in assessing patients for potential limb salvage is determining which nerves need to be sacrificed and which can be preserved.

Clearly, the sciatic nerve is the most important of all, and inability to save the sciatic nerve is considered an indication for amputation. The sciatic nerve has nerve root contributions from the L-4, L-5, S-1, S-2, S-3 levels. The L-4 and L-5 roots form a conjoined root traveling anterior to the sacrum at the S-1 level that is intimately associated with the sacrum and the anterior portion of the SI joint before dividing posteriorly to enter the sciatic notch. The sacral contributions exit the sacral foramen anteriorly at their respective levels, transversing laterally to join with the L-4, L-5 root within the sciatic notch. Malalignments of the ilium and ischium with extensive soft-tissue extension either extrapelvically or intrapelvically near the sciatic notch usually require sacrifice of the entire sciatic nerve. This renders the lower leg functionless and insensate, and it also sacrifices the neurologic function to all of the gluteal muscles. Lesions involving the lower portion of the ischium or proximal femur may also have soft-tissue extensions near the sciatic nerve. Fortunately, the farther the nerve gets from the sciatic notch, the more mobile it becomes, making a greater latitude of nerve displacement possible. In many cases, although the nerve is displaced, it still can be preserved. This is certainly in contrast to the tight anatomic confines of the nerve within the sciatic notch itself.

Lesions that involve the anterior portion of the pelvis, including those tumors arising within the pubis or anterior portion of the acetabulum or ilium, potentially involve the femoral nerve. Within the pelvis, the femoral nerve lies between the iliacus and iliopsoas muscles, and there is a certain amount of potential for it to be displaced by masses in this area. It is most tightly confined where it passes beneath the inguinal ligament and over the pubis near the iliopectineal eminence. Large lesions in this area may require sacrifice of the femoral nerve, but in contrast to sacrifice of the sciatic nerve, this is not necessarily a contraindication to limb salvage.

Experiences with total hemipelvectomy are limited, but the duration of these protheses is reliable. The most critical consideration following total hemipelvectomy is the potential for arterial thrombosis and occlusion, nerve compression, or neuropathy. A sling or plaster splint is needed for a longer time than for other anatomic areas, management of pelvic lesions was still fraught with higher complication rates and less satisfactory functional results (52, 53, 125, 127). The renal mass effect and the pelvic mass effect that characterized pelvic tumors were often no better tolerated than the retroperitoneal mass effect, and the impetus to extend the indications for limb salvage to include even large pelvic lesions, provided some sort of functioning extremity could be preserved. Anatomical approaches and reconstructive techniques eventually became more standardized, and a limb-salvage approach for many pelvic lesions developed. Furthermore, the development of computed tomography and magnetic resonance imaging allowed better comparison of functional results achieved with conservative limb salvage techniques (50). With more recent improvements in spinal fixation techniques, reconstruction for lesions involving the sacrococcygeal area and even some lesions requiring resection of the portion of the spine are possible in selected patients.
courses over the top of the posas muscle and, at the level of the bifurcation of the great vessels, lies lateral to them. It crosses anterior to the common iliac vessels near the origin of the external and iliac branches, and from there the ureter lies in a medial position and begins to deviate from the vessels as it courses to the bladder. It is important to identify the ureter in any retropertioneal dissection in this area. It is possible to identify it intraperitoneally by testing for peristalsis, but for lesions with larger intrapelvic masses, preoperative placement of a ureteral stent can help, particularly if you suspect it may be displaced from its normal anatomic position. The bladder itself can be involved with larger intrapelvic masses, although more often than not it tends to be displaced and easily separated from tumor masses. Certainly, with distinct bladder involvement, a urologic surgeon’s assistance is required because portions of the bladder can also be resected en bloc with the lesion.

**EVALUATION AND BIOPSY**

As with other malignancies of the musculoskeletal system, patients with pelvic neoplasms usually present with pain, a mass, or both. The development of a mass may go undetected for long periods of time, particularly if it is in an intrapelvic location, but even an extrapelvic mass or proximal femoral mass can go undetected. In contrast to lesions occurring more distally in the extremity, where peripheral nerves are more mobile, neurologic symptoms arising from pelvic lesions are not uncommon. Radicular pain from compression of the sciatic nerve or lumbosacral nerve roots can arise from lesions posterior to the hip joint or in the sacroiliac area due to the retroperitoneal origins of the nerves. Such symptoms can be mistaken for low back pain or referred pain from the referenced area. It is not uncommon for a patient with a pelvic neoplasm to have undergone previous lumbar disectomy without relief of symptoms before the true etiology of the pain is identified.

When performing physical exams on patients with suspected pelvic neoplasms, the objective is to localize the area of pain and tenderness, identify soft-tissue masses, and evaluate the neuromuscular function of the extremity. The presence of a mass either intrapelvically or extrapelvically in patients with pelvic pain is usually a sign of malignancy and should be evaluated accordingly. The evaluation of neurologic compromise, particularly if it corresponds to a particular level, is helpful in directing further studies. Bowel and bladder compromise is rare in patients with lesions of the pelvis because sufficient innervation from the contralateral side will maintain neurologic function. Significant alteration in bowel or bladder function suggests a higher lesion, one involving the sacrum or spine itself.

A good-quality plain radiograph is the first step in the radiographic evaluation. The fact that interpretation of plain films is sometimes difficult because of the complex anatomy, as well as overlying bowel and gas, is no reason not to obtain them. An initial diagnostic impression and reasonable differential diagnosis can generally be made after examining the plain radiographs. In patients under 30 years of age, destructive lesions of the pelvis and proximal femur are generally the result of osteosarcoma or Ewing’s sarcoma. Benign lesions, such as aneurysmal bone cysts or giant cell tumor, are also possible and occasionally can have an aggressive appearance that warrants further radiographic evaluation. Large osteochondromas can also arise from the proximal femur and pelvis and may even produce a palpable mass. These patients are often already aware of the presence of an osteochondroma. If they have the impression that it is enlarging, though, malignant degeneration is a concern. As patients become older, the possibility of metastasis from carcinoma or myeloma is more likely. Certainly if one suspects metastasis, the diagnostic strategy should include looking for other lesions or other primary lesions.

Chondrosarcoma is one of the more common primary malignancies of the pelvis, particularly in patients over 40 years of age. These malignancies can present as intramedullary lytic lesions in the pelvis or proximal femur and are not necessarily associated with the distinctive calcific pattern generally attributed to these lesions. Certainly with patients having destructive lesions of the pelvis associated with a large soft-tissue mass containing fluffy and floculent calcifications, a chondrosarcoma should be suspected. In fact, it is possible to confidently diagnose many of these lesions solely from plain film findings.

However, the identification of sacral lesions on plain films can be particularly difficult, even with good-quality radiographs. If you suspect a sacral lesion, further diagnostic imaging is in order. CT scans are particularly helpful in evaluation of pelvic lesions like the plain film and CT images are best at defining bony abnormalities and less effective in determining soft-tissue or intramedullary disease. As such they complement the plain film in determining the extent of cortical destruction and the presence of soft-tissue calcification. A CT scan is more often used for pelvic and spinal lesions and than for lesions because it is so difficult to visualize the complex three-dimensional anatomy of the pelvis and spine from plain films alone. Once again, certain lesions can be diagnosed with certainty from CT findings. For example, the calcific pattern associated with cartilage lesions can be identified effectively with a CT scan. Other lesions, such as aneurysmal bone cysts, can be effectively diagnosed with CT imaging if typical fluid levels are identified.

An MRI is essential in evaluating potential primary malignancies of the pelvis or proximal femur. The intrasosseous or medullary extent of lesions can be accurately identified and often will be more extensive than one might presume from examining plain film or CT findings. Soft-tissue extension, both intrapelvically and extrapelvically, is well assessed with an MRI, especially the proximity to neurovascular structures. Furthermore, the MRI is excellent at assessing lesions that may involve the sacrum or lower spine because it can accurately image the spinal canal and potential involvement of nerve roots. In general, plain film and the CT scan give the most information regarding the actual character or histologic diagnosis of a lesion, whereas the MRI gives the most information regarding anatomic staging or the resectability of a lesion.

Systemic evaluation for patients with pelvic malignancies is similar to other anatomic areas. Technetium-99 bone scans can identify the source of other bony lesions, but they tend not to give any further information regarding the local disease. A thorough evaluation of the chest with chest radiographs and a CT scan is important in determining potential pulmonary involvement. Specialized tests that may be unique to pelvic neoplasms include angiography and tests to determine urologic function. Significant alteration in bowel or bladder function suggests a higher lesion, one involving the sacrum or spine itself.

The evaluation of urologic function is done either with an intravenous pyelogram (IVP) or more directly with cystoscopy. Prior to CT and MRI, the IVP was perhaps more valuable in determining displacement of the ureter or bladder. For these purposes, the MRI and CT scan are currently used more often. Cystoscopy can be helpful in determining actual bladder involvement, as it provides direct visualization. It is also helpful if a ureteral stent is placed to aid in the intraoperative localization of the ureter.

Once the patient has been evaluated radiologically, a biopsy is indicated to establish histologic diagnosis. There are many biopsy techniques available, and the actual technique used depends on the size and location of the lesion and, to some degree, on its suspected histologic diagnosis. For a patient with a known primary lesion and suspected metastasis, a simple fine-needle aspirate with or without CT guidance is acceptable. If the lesion is indeterminate, however, and certainly if you suspect a primary malignancy of the pelvis, the specific biopsy technique employed should allow for potential limb salvage.

The biopsy location in the pelvis is somewhat more complex than for lesions in the long bones. It is mandatory to have an understanding of the incisions and surgical approaches required for a pelvic limb salvage prior to biopsy of any of these lesions. An inappropriately placed biopsy, particularly one directly through the midportion of the gluteus muscle to get at an iliac or ileal lesion, can compromise the large gluteal flap that is often used in pelvic resections. In general, for lesions in the ilium, place the biopsy track along the iliac crest from the posterior superior iliac spine anteriorly up to the anterior superior iliac spine. For lesions of the sacrum, a biopsy track close to the midline posteriorly is preferable. The biopsy track for lesions involving the anterior pelvis in the area of the pubis or symphysis should be along the line of the ilioinguinal ligament, either lateral to the femoral nerve or medial to the femoral vessels near the pubic tubercle or symphysis pubis. If the mass is in the interpelvic portion of the ilium or pubis, try to keep the biopsy track in an extrapelvonal location, which again means staying close to the iliac crest line. Biopsy lesions involving the external iliac, obturator, or pubic rami, or lesions from an anterior, inferior direction, are shown as shaded regions in Figure 126.43. Lesions of the proximal femur can be biopsied directly lateral on a line anywhere from the tip of the greater trochanter down the shaft of the femur.

![Figure 126.43](image-url)
Depending on the location of the soft-tissue mass or the extent of resection needed, it is also possible to biopsy lesions along a line corresponding to the Smith-Peterson interval. This extends from the anterosuperior iliac spine, anteriorly and laterally across the thigh, in the interval between the tensor fascia muscle laterally and the sartorius and rectus medially. Lesions located along the medial acetabular wall and sciatic notch are in a very difficult area to biopsy, at least with sound one-dimensional techniques. Unless extension of the mass anterior to the level of the pelvic brim, it can be very difficult to reach from an intrapelvic biopsy placed along the wing of the ilium. Posteriorly directed biopsies through the sciatic notch potentially contaminate important neural structures. Under such circumstances, a consultation with an orthopaedic oncologist is indicated to determine the biopsy path that has the least anatomic and oncologic complications.

**OPERATIVE TECHNIQUES**

**Classification of Resections**

Enneking and Dunham (55) classified pelvic resections into three basic types, I, II, and III (Fig. 126.44). As previously mentioned, the classification is based on the zones of the pelvis that are removed rather than on actual anatomic bones. Type I resections are iliac wing resections, type II resections are acetabular resections, and type III are pubic rami or obturator resections. Enneking and Dunham initially used the letter A to further classify more extended resections. For example, a type IA resection includes the iliac wing plus the gluteal muscles, a type IIA resection includes the acetabulum as well as the proximal femur as an extra-articular resection of the hip, and a type IIA resection includes the iliopsoas and femoral nerve. Since their original article, this basic classification system has been modified. A type IV resection has been added that is used to classify those resections that also include a portion of the sacrum, such as an iliosacral resection. These classifications not only provide a more uniform system for describing the resections, but also help to determine the optimal position for the patient for surgery and the surgical incision required.

![Classification of pelvic resections.](image1)

**Surgical Exposure**

Despite its anatomic complexity, virtually all of the pelvis can be safely exposed and removed through a fairly basic set of incisions (Fig. 126.43, Fig. 126.45). The standard or utilitarian incision is useful for most iliac and acetabular resections. The incision is similar to that used for an extended iliofemoral approach (67).

![Posterior view of incisions for pelvic resections. A: The posterior limb of the iliofemoral and ilioinguinal incision. B: The midline spine incision. The overlying shading shows the areas where biopsy track should be placed.](image2)
Resections of the pelvis involving removal of the acetabulum

Type II Resections and Reconstructions

Type I resections of the ilium are indicated for lesions that involve the iliac wing and the immediate adjacent soft-tissue structures. Type I resections tend to be used with small lesions because a clear bony margin must exist in the supraacetabular area to allow for a line of resection. The posterior resection is made at or near the sacroiliac joint. An important factor for these resections is whether a posteromedial strut of bone can be preserved, thereby maintaining structural continuity between the acetabulum and the sacrum. Figure 126.46 is an example of such a resection: Under the circumstances illustrated, no reconstruction is needed. If a complete resection is done through the sciatic notch, reconstructive options include (a) doing nothing, or (b) attempting to restore pelvic continuity with either autograft or allograft. Without reconstruction or with only minimal attempts at reconstruction—hinging the pelvis on the symphysis and approximating the remaining ischium to the sacrum—patients will develop a pseudarthrosis in this area. Most patients will have only minimal pain, but they will be left with a slightly shortened extremity. A better functional result can be achieved by reconstructing continuity of the pelvic ring (4,35,98). Autograft or allograft struts, either of fibula or, perhaps, iliac crest, can be wedged into the defect with internal fixation in the form of plate and screws to stabilize the pelvis until the graft heals (Figure 126.47).

In the experience of Enneking and Dunham (35), 10 of 13 patients with type I or IA resections had a good functional result, although if pelvic continuity was lost, only 2 of 4 had a good result. The experience at the Mayo Clinic was similar. Out of 17 iliosacral resections, the best results were in the 12 patients who were left with a stable pelvis or who had a solid arthrodesis—and none of them had less than a good result. On the other hand, only 1 of the 5 patients with a pseudarthrosis or without reconstruction had a good result (98).

With more extensive resections of the sacrum, simple iliosacral fusion can be difficult because there is sacral bone loss. Extending the arthrodesis to the lumbar spine may be necessary. In these circumstances, spinal fixation instrumentation can be used with special modifications to allow fixation out to the ilium (Figure 126.48).

Type II Resections and Reconstructions

Resections of the pelvis involving removal of the acetabulum en bloc are the most challenging not only from a surgical removal standpoint, but also from a
reconstructive standpoint. Whereas one can expect a reasonably good functional result after type I or type III resections alone, any resection involving the acetabulum generally has significant functional implications.

A type II resection is indicated for those lesions that involve all or a portion of the acetabulum and for those lesions that involve the hip joint proper, whether the lesion arises primarily within the pelvis, soft tissue, or proximal femur. For lesions that do arise within the pelvis itself, it is unusual to be able to do only a type II resection. Most type II resections are done either in combination with the iliac wing as a type III or in combination with the anterior arch of the pelvis as a type II/III.

Exposure for type II resections is generally obtained through the extensile ilioinguinal and iliofemoral approaches, using the T-type incision anteriorly. Adequate exposure of the iliopectineal and retropelvisal structures is gained through the ilioinguinal portion of the dissection. The degree of soft-tissue extension into the pelvis determines the difficulty of dissection as well as the need to sacrifice important structures. In general, it is possible to preserve the external iliac vessels, as well as the femoral nerve, dissect them carefully away from any tumor mass. Ligation of the internal iliac vessels is often necessary, not only for adequate oncologic margins, but also to aid in getting the external iliac vessels away from any tumor mass. Once the tethering effects of the internal iliac vessels are removed, the external iliac vessels can easily be displaced medially.

- Divide the iliacus and psoas muscles near the intended level of bony resection, and identify the superior aspect of the sciatic notch.
- Use the lower portion of the ilioinguinal approach to identify the superior pubic rami and its intended resection level. The obturator nerve and vessels are generally sacrificed, particularly if there is any intrapelvic extension of tumor. The iliofemoral portion of the exposure completes the extrapelvic portion of the exposure. Not only are the lines of the iliac and ischial osteotomies determined, but exposure of the entire hip capsule circumferentially is possible.
- For intra-articular resection, make a circumferential capsular arthrothrystomy and dislocate the hip. A complete dissection of the sciatic nerve, from its exit through the sciatic notch to the proximal thigh, is possible.
- Complete removal of the acetabulum also requires a sectioning of the sacrospinous ligament. Take care to preserve the pudendal nerve, if possible, and the internal pudendal vessels.

Reconstruction after type II resection depends primarily on the actual amount of bone stock remaining. In principle, just as in other anatomic areas, the options include a flail joint, a stable arthrodesis, or a functioning arthroplasty. Early experiences with limb salvage of periacetabular lesions, before the development of effective reconstructive techniques, generally resulted in a flail hip joint (3, 126). This also left the patient with a shortened extremity and a somewhat unstable hip, but it was preferable to a hemipelvectomy. There may still be indications for no reconstruction or an attempt to achieve a stable pseudarthrosis with minimal reconstruction. Normally this would occur when all or most of the hemipelvis was removed. Most authors agree that functional results are certainly improved and pelvic continuity can in some way be restored (38, 98, 130).

Arthrodesis

Arthrodesis of the proximal femur to a remaining portion of the pelvis can be an effective way of restoring function. Depending on the amount of bone removed, fuse the proximal femur either to the ilium as an iliofemoral fusion or, if the majority of the ilium has been resected, the proximal femur to the remaining ischium as an ischiofemoral arthrodesis. With an iliofemoral arthrodesis, fit the proximal femur onto the remaining ilium and, in most cases, secure it in a place with a 4.5 mm cobra plate (Figure 126.49). The greater trochanter of the femur can be osteotomized so that the plate fits more in line with the femur. The iliac fixation is, generally, on the outer table of the ilium, but it can be on the inner table if need be. Although this results in a shortened extremity, it produces a good functional result if successful.

Unfortunately, fusion can be difficult, with a pseudarthrosis rate of at least 50%. In some patients, the pseudarthrosis is stable and minimally painful, and they may end up with a reasonably functional result. Experience from the Rizzoli Institute actually suggests that the functional result from a stable pseudarthrosis was very similar to that of a solid arthrodesis (15). These results suggested that minimal internal fixation, in the form of wiring the femur to the remaining ilium, may be preferable. This generally led to a firm pseudarthrosis and minimized the overall complication rate associated with failed fixation. To avoid the invariable limb shortening associated with a direct iliofemoral arthrodesis or attempted pseudarthrosis, an intercalary allograft can be used. Fusion, however, is still difficult, with a high rate of ultimate failure through nonunion or infection (15, 98).

Ischiofemoral fusion can also result in a good functional outcome for patients who require periacetabular resections along with the majority of the iliac wing. In this instance, the proximal femur is fixed to the remaining ischium, generally with large fragment screws or wire cerclage (Figure 126.50). Successful patients generally have a good functional result, with less limb shortening than would be associated with an iliofemoral arthrodesis. The difficulty lies in actually obtaining the arthrodesis. The fusion rate is lower than that seen with iliofemoral arthrodesis. Additionally, postoperative pain at the symphysis pubis from the high stresses in this area combined with a very poor functional outcome if a pseudarthrosis occurs have led many physicians to avoid the ischiofemoral arthrodesis.

Arthroplasty

Hip arthroplasty for type II periacetabular resection can be achieved with either an endoprosthesis osteoarticular pelvic allograft or prosthetic bone graft composites. The type of arthroplasty performed is based on remaining bone stock, as well as physician and patient preferences.

Endoprosthesis

Perhaps the most straightforward endoprosthetic reconstruction, as long as adequate ilium remains, is the use of saddle prosthesis. The saddle prosthesis was
Obtain exposure for resection of lesions involving the pubic rami and obturator foramen through the ilioinguinal incision, with or without its posterior extension along the posterior column just inferior to the acetabulum (Figure 126.51). This articulating piece is connected to a relatively standard femoral prosthesis on the femoral head taper. Body segments can also be added in between to restore adequate limb length. Abduction and flexion/extension are achieved at the prosthesis–bone interface, with rotation achieved within the articulating prosthetic segment itself. Soft-tissue reconstruction is critical to provide stability of the prosthesis within the iliac notch. The early experience of Nieder et al. (90,97) with this prosthesis was primarily for patients with massive bone loss due to failed total joint arthroplasty. More recently, the prosthesis has been used in patients after periacetabular resections. Aboulafia et al. (1) reported on their experience with 17 patients, of whom 12 had overall good to excellent functional outcomes. In general, the functional level result is certainly not as good as a conventional hip arthroplasty, but it is much better than a flail hip and more predictable than attempts at iliofemoral arthrodesis.

Figure 126.51. Type III pelvic resection with reconstruction using a saddle prosthesis. A: AP radiograph of the hip showing a large chondrosarcoma involving the entire obturator foramen. The lesion is primarily situated within the superior pubic rami, but it clearly extends to the acetabulum. B: CT scan illustrating extensive destruction of the medial acetabulum along with soft-tissue masses both within the pelvis and extending through the obturator foramen. C: A resection required removal of the entire acetabulum, and the reconstruction was performed with a saddle prosthesis.

A more complex method of pelvic reconstruction after acetabular resection involves the use of the pelvic endoprosthesis incorporating an actual hip joint near the anatomical center of the native joint (2,45,95,135,144). This prosthesis can be made as a custom implant or as a modular implant, allowing some intraoperative flexibility. By reproducing the normal hip center, Windhager et al. (144) felt their functional results were better than their experience with the saddle prosthesis. The advantage of these systems over using allografts or attempting to obtain an arthrodesis is a tendency toward fewer early complications, less morbidity, and an earlier functional return. This is particularly important in a patient with a high-grade malignancy of the pelvis who may have limited survival.

Biologic Arthroplasty

Hemipelvic allografts or autoclaved autografts is another method of reconstruction for periacetabular resections (6,28,49,92). These techniques again have the advantage of reproducing a more normal hip joint center and limb length, but they are also associated with a longer operative time and increased morbidity. The use of a hemipelvic or whole acetabular allograft requires being able to procure a graft, normally from a large regional or national bone bank, of the appropriate size to match the defect created after resection. The graft is normally fixed to the remaining host bone with a combination of plates and screws or large Steinmann pins. Perform a conventional hip arthroplasty, creating an allograft–prosthesis composite (Figure 126.52). Keep reaming of the acetabulum to a minimum to avoid excessive weakening of the graft. Now cement the acetabular component into place. Alternatively, use a bipolar prosthesis, thus eliminating any reaming of the allograft bone. It is certainly possible to replace the entire hip joint, including a segment of proximal femur, as a complete osteoarticular graft, although experience with this has generally led to failure, and most authors suggest using a prosthesis for the hip joint itself.

Figure 126.52. Reconstruction of a type II pelvic resection with a whole acetabular allograft. Fix the allograft to the ilium and pubis with plate and screw fixation and interfragmentary screws as necessary. Then perform a total hip arthroplasty, cementing the acetabular cup into the allograft bone.

Some centers use the technique of autoclaving the resected specimen and reimplanting it. After resecting the specimen, clean it of any soft tissue and tumor and autoclave it at 135°C for approximately 10 minutes. Reinsert it into the original bed and fix it securely with plates or threaded Steinmann pins. Clearly, if the tumor itself has already destroyed a lot of the actual bone, the technique would not be useful. Therefore, it is generally reserved for those lesions with minimal bone destruction.

Many of the published reports on the use of allografts or autoclaved autografts suggest a number of potential problems, including infection, dislocation, and graft failure through resorption, fracture, or prosthetic loosening (17,49,95,101). Harrington (49) reported on 14 patients, 10 of whom had reconstruction with an allograft and 4 of whom had the autoclaved autograft technique. Although he reported only one infection and one local recurrence, there were still three patients with late fracture of the grafts. The experience reported by Bell et al. (6), on 17 patients with pelvic allografts, also points out the potential difficulties with these reconstructions. They noted a local recurrence in three patients, deep infection in two, and dislocation of the hip in five. Overall, these results are not dramatically different from those achieved with reconstructions by other methods and serve to illustrate the difficulty of restoring function in periacetabular resections. In spite of the morbidity, attempts at reconstruction are generally worthwhile because the functional results are considerably better than leaving the hip flail.

Type III Resections and Reconstructions

Obtain exposure for resection of lesions involving the pubic rami and obturator foramen through the ilioinguinal incision, with or without its posterior extension along the inferior pubic rami.

- After completing the intrapelvic and extrapelvic dissection, determine the lines of bony resection.
- The osteotomy through the symphysis pubis or even the contralateral side is generally made with a Gigli saw. Take care to protect the urethra from injury.
- Laterally, the superior pubic rami can be cut at any level, even to the point of resecting a portion of the anteroinferior acetabulum. Provided this is a minor amount of acetabulum, it will not compromise hip stability. It is usual to be able to preserve and protect the femoral vessels and femoral nerve throughout the dissection. It is very common, however, to have to sacrifice the obturator nerve, as mentioned previously.
- Make the posterior osteotomy anywhere along the inferior pubic rami as determined by the tumor extent, even to the point of making the resection through the posterior column just inferior to the acetabulum (Figure 126.53).
You can usually palpate the sulcus just inferior to the acetabular lip, and this serves as a landmark to the inferior portion of the acetabulum. Expose the posterolateral column circumferentially through the lesser trochanter, preserving either through a Gigi saw or an osteotomy to make the cut. Generally, the resection can be made without dislocation of the hip, but if need be, dislocate the hip temporarily.

Reconstruction after type III resections is generally unnecessary because continuity between the femur and the sacrum is maintained ([Figure 126.53]). This is borne out by the experience of most authors, who show that functional results are generally good to excellent in the absence of any reconstruction ([14,35,38,98]). Soft-tissue closure after type III resections is particularly important. You must reconstruct the lower abdominal wall, normally by suturing the ilioinguinal detachment to the adductor muscles of the thigh. Be careful during the repair to allow plenty of room for the superficial femoral vessels as well as the spermatic cord. Because the pelvic floor is disrupted, there does tend to be a settling and a slight shift of abdominal contents into the area and, potentially, even into the upper thigh, but this is generally asymptomatic.

**ONCOLOGIC OUTCOME OF PELVIC LESIONS**

The overall oncologic outcome of pelvic lesions depends on a number of factors, including the location and grade of the lesion as well as the ability to achieve a wide surgical margin. These principles are similar to those for malignancies that occur in other areas, and they are discussed in Chapter 128, Chapter 129 and Chapter 130. The pelvis is somewhat unique in that its anatomic complexities tend to make it more difficult to achieve a wide surgical margin. This is particularly evident in lesions that occur in the iliosacral area, because the margin for either may be similar, whether an amputation or a limb salvage procedure was done. Local recurrence rates after pelvic resections do tend to be higher than for extremity lesions. Overall, reports show local recurrence rates for lesions occurring in the pelvis to be in the range of 5% to more than 30% ([6,14,35,58,98,118]). The highest local recurrence rates are generally for iliosacral lesions. If you can achieve wide margins, the local recurrence rate is distinctly lower, usually less than 20%. When a marginal or lesions margin is achieved, the local recurrence rate tends to be closer to 50% or even higher.

Overall survival of patients with pelvic lesions depends primarily on the grade of the lesion. In general, patients with high-grade lesions of the pelvis tend to have a poorer prognosis than those with extremity lesions. In the series by both Shin et al. ([118]) and Kawai et al. ([67]), overall survival in patients with high-grade sarcoma of the pelvis was less than 35%.

**PROXIMAL FEMORAL RESECTIONS AND RECONSTRUCTIONS**

The proximal end of the femur is one of the more common locations for primary bone tumors. In children and young adults, the most common lesions include osteosarcoma and Ewing's sarcoma, whereas in patients over 40 years old chondrosarcoma is more likely. The proximal femur is also a common site for metastasis and myeloma, and, occasionally, proximal femoral resections are required to manage these lesions as well. Most lesions of the proximal femur are amenable to limb salvage because only with the most extensive soft-tissue involvement are any important neurovascular structures involved. The femoral vessels lie far enough anterior and medial to the femur itself that they are not normally a problem and, as mentioned earlier, the sciatic nerve at this level is not only well away from the femur but also mobile enough to make tumor involvement rare. Furthermore, because the functional results of hip disarticulation or hemipelvectomy are so poor, any reconstruction that provides a hip stable enough to allow reasonable knee and foot function would be worthwhile.

Proximal femoral resections are generally classified as intra-articular or extra-articular. For intra-articular resection, the acetabulum is preserved in its entirety, and reconstruction with a functional arthroplasty is generally possible. In an extra-articular resection, the entire joint is removed, including the acetabular articular surface. If this can be done by removing only a shell of the acetabulum without totally disrupting pelvic continuity, reconstruction with arthroplasty is also possible. If the entire acetabulum is removed, thereby disrupting pelvic continuity, the reconstructive challenges are similar to those encountered with type II pelvic resection.

- It is unusual to do the resection in a lateral position with a long, straight, lateral incision that incorporates the biopsy track.
- Split the tensor fascia lata longitudinally; it can generally be preserved.
- Detach the gluteus medius and minimus from the greater trochanter, preserving as much length as possible depending on tumor extent. The origin of the vastus lateralis muscle is normally left with the specimen, but often a significant amount of the muscle itself can be preserved. Provided a cuff of the muscle is left adjacent to the femur, reflect the more superficial portion of the vastus lateralis anteriorly; it can be very useful in soft-tissue reconstruction.
- Expose the anterior aspect by externally rotating the femur. Variable amounts of rectus femoris will need to be resected or released, depending on tumor extent. The sartorius muscle spans the area of resection and therefore can generally be preserved.
- It is usual to transect the ilioinguinal nerve at the level of the hip capsule. Only with very large lesions will you need to expose the femoral vessels themselves.
- For soft-tissue reconstruction, expose the posterior aspect of the femur. Detach the short external rotators, quadratus femoris, and glutus maximus from the femur, leaving a cuff of muscle.
- You can generally palpate the sciatic nerve, and often it is not necessary to expose it directly.
- Osteosarcoma and the femur at the intended level of resection facilitates medial exposure of the femur. The proximal femur becomes much more mobile, and it is possible to transect the adductor muscles appropriately.
- If the resection is to be intra-articular, incise the hip capsule circumferentially.
- Cut the gluteus medius tendon and remove the specimen.
- The options for reconstruction after proximal femoral resection depend primarily on whether the resection has been done with intra-articular or extra-articular margins. Intra-articular resections are generally amenable to arthroplasty, and patients generally prefer this. Perform the arthroplasty with an osteoarticular allograft, an osteoarticular prosthesis composite, or an endoprosthetic reconstruction.
- When an osteoarticular allograft is planned, it is important to select a graft of the appropriate size, particularly the femoral head dimensions. Test the femoral head articulation within the acetabulum intraoperatively to ensure that it is the proper size. A femoral head too large or too small generally leads to problems, and one can decide to reconstruct with an allograft prosthesis composite if need be.
- To do the soft-tissue reconstruction around the hip, suture the remnants of the patient's capsule to the capsule that is attached to the allograft.
- Bony fixation to the host bone is generally done with the large fragment plate and screw fixation.

The results of osteoarticular allograft reconstruction of the proximal femur are somewhat unpredictable ([120]). With 15 patients treated with osteoarticular allograft, Joffe et al. ([25]) noted nonunion and fracture in five patients, infection in four, and an unstable hip in one. Of the 15 patients, 10 required reoperation for complications. Generally, reconstruction with an allograft prosthesis composite provides a better functional result with fewer complications than an osteoarticular allograft alone. The composite reconstruction provides the advantages of the allograft in terms of soft-tissue attachment, and also the more predictable return of function with fewer of the complications associated with an endoprosthesis. The specifics of the composite construct depend on the length of femur resected. From a biomechanical standpoint, it is considered unwise to have the tip of the prosthesis at or near the allograft–host junction.

- If the femoral resection is long, cement a standard hip component into the allograft, then fix the entire composite to the distal femur with a plate and screws. The plate should be long enough to overlap the stem by a few centimeters to attempt to alleviate any stress riser effect near the tip of the femoral stem.
- If the resection length is shorter, use a long-stem femoral component. Once again, cement the allograft to the proximal portion of the stem, and insert the entire composite into the distal femur.
- A press-fitting of the stem in a noncemented fashion achieves fixation in the host bone. If needed, add a plate to the allograft host junction for additional stability.
The articular portion of the reconstruction can be done with a standard acetabular component or as a bipolar arthroplasty.

The allograft prosthesis composite reconstruction typically fares better than the osteoarticular graft. Joffe et al. (55) reported on 13 patients with allograft prosthesis composite reconstruction. These patients had a much lower incidence of graft-related complications and had an overall better functional result than did the osteoarticular grafts. In addition, in a number of their patients, failures of osteoarticular graft were salvaged with allograft prosthesis composites. Giletiis and Pliasseci (44) reported on their experience with allograft prosthesis composite and 11 reconstructions of the hip. In an average follow-up of almost 4 years, they reported overall good functional results and no implant revisions as a result of loosening.

Probably the most common method of reconstruction after proximal femoral resection uses an endoprosthetic device (Figure 126.54) (119). The prosthesis is either a one-piece design or a more recent, modular system, which allows intraoperative customization of length. This makes some intraoperative flexibility possible, as does an allograft prosthesis composite. The fixation stems can vary in length and diameter, and they can be straight or bowed to accommodate whatever remains of the patients’ femur. These prostheses are generally cemented in place, although noncemented designs have shown effectiveness as well. Once the prosthesis is in place, soft-tissue reconstruction is critical in minimizing complications and improving function.

**Figure 126.54.** Proximal femoral resection and endoprosthetic reconstruction. A: AP radiograph of the proximal femur showing a lytic lesion within the femoral neck and head in a 19-year-old woman. B: T1-weighted coronal MRI showing a lesion within the proximal femur, which eventually proved to be osteosarcoma. C: AP radiograph of the proximal femur after proximal femoral resection and endoprosthetic reconstruction with a modular proximal femoral prosthesis.

- Secure whatever capsular structures remain around the neck of the prosthesis, generally in purse-string fashion, to improve stability.
- Pull the abductor muscles and tendons distally as far as possible and secure them to the prosthesis with a loop or other fixation at a point near the old greater trochanter.
- Use the remaining muscles of the thigh to cover up the entire prosthesis with healthy, viable muscle.
- Pull the vastus lateralis proximally and laterally as far as possible and secure it either to the abductor muscle or to the underside of the tensor.
- Farther down the thigh, suture the vastus lateralis to a hamstrings, if it has been mobilized, or to the lateral intramuscular septum.
- Pull the gluteus maximus muscle anteriorly and suture it to the remaining vastus as well.
- With some diligence, the prosthesis can generally be covered, which aids in preventing deep infection and improves function by getting the muscle back out to a more physiologic length.

The experience with these megaprostheses has generally been favorable. Multiple series have been reported with various prosthetic designs (32,51,62,70,76,121,126,134,137). The most common complication seems to be dislocation, which is reported in up to 25% of patients. Reoperation for mechanical failure or loosening has been very low, less than 15%, and failure due to deep infection was also low, usually less than 5%. The functional results of endoprosthetic devices are quite good in terms of pain relief. The main functional problem is still the relative lack of abductor strength. This is certainly quite variable and depends on the number of abductors that are still available for reconstruction and the ability of the surgeon to get satisfactory healing into the surrounding soft tissues. In this regard, the allograft prosthetic devices may have a benefit.

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Benign tumors of the musculoskeletal system represent a diverse group of clinical entities, varying greatly in their behavior and thus treatment requirements. Some lesions may simply be observed indefinitely, while others demand wide resection and reconstruction. While benign bone tumors do not as a rule metastasize, they may at times act very aggressively locally and be mistaken for malignant tumors. On rare occasions, benign tumors may be multifocal or associated with pulmonary metastases. It is incumbent upon the treating orthopaedic surgeon to be familiar with the spectrum of benign bone tumors and tumor-like conditions in order to provide the appropriate management (Table 127.1). In this chapter, the most common benign, primary tumors and tumor-like conditions of bone across all age groups will be discussed as to their general and surgical management.

STAGING

Enneking et al. (46,47) described the most widely used staging system for benign bone tumors (Table 127.2). The stages are denoted by the Arabic numerals 1, 2, and 3, whereas malignant bone tumors are classified by Roman numerals (I, II, III). As will be detailed later, many benign bone tumors have the potential to present at, and progress through, various stages during their disease course.
Stage 1 or latent tumors are often discovered incidentally and usually do not progress. They may even spontaneously resolve. These tumors are noninvasive with distinct margins. Latent tumors can often be treated with observation alone. When surgical intervention is necessary, intralesional excision or simple curettage will suffice. Examples of stage 1 tumors are nonossifying fibroma, enchondroma, unicameral bone cyst, osteochondroma, osteoid osteoma, eosinophilic granuloma, and fibrous dysplasia.

Stage 2 or active tumors differ from latent tumors in that they usually are not self-limiting and tend not to resolve without intervention. These lesions expand or deform the host bone but remain contained in the bone. They have the potential to destroy the cortex, invade the surrounding soft tissues, and recur if residual tumor is left behind. Active lesions are most often treated with intralesional curettage. The procedure may be augmented with some type of adjuvant therapy to extend the margins if deemed necessary. Examples of stage 2 tumors are enchondroma, osteochondroma, osteoid osteoma, giant cell tumor, chondromyxoid fibroma, fibrous dysplasia, eosinophilic granuloma, aneurysmal bone cyst, osteofibrous dysplasia, and unicameral bone cyst.

Stage 3 or aggressive tumors extend beyond the bone into the adjacent soft tissues. These lesions can be so destructive that they mimic malignant tumors. Because of their extensive cortical destruction, it is not uncommon for stage 3 tumors to present with pathologic fracture. Aggressive tumors are best treated with en bloc resection when possible, or a very aggressive and thorough curettage. When these tumors are treated by intralesional excision because of anatomic restraints, they will almost always require some form of adjuvant therapy and are associated with a fairly high recurrence rate. Examples of stage 3 tumors are giant cell tumor, osteoblastoma, chondroblastoma, and aneurysmal bone cyst.

Benign lesions may “recur.” In general, recurrence refers to the persistence and subsequent growth of microscopic disease left over from the initial procedure.

OSTEOID OSTEOMA

CLINICAL AND RADIOGRAPHIC PRESENTATION

Osteoid osteoma is a benign tumor consisting of a well-demarcated bone-forming lesion called a nidus, surrounded by a radiodense, reactive zone of host woven or lamellar bone. The surrounding secondary bony reactive zone represents a reversible change that remodels and regresses after the nidus is removed. The nidus has limited growth potential and rarely exceeds 1 cm in diameter. Lesions larger than 1.5 cm in diameter have been arbitrarily designated osteoblastomas. Osteoid osteoma accounts for 10% to 13% of all benign bone tumors and 2% to 3% of all primary bone neoplasms (51,65,164). It is most commonly seen in the second and third decades of life, with a male to female predominance of approximately 3 to 1. Over half of these lesions occur in the long bones of the lower extremity, with the proximal femur being the most common location. In the spine, osteoid osteomas almost exclusively occur in the posterior elements of the lumbar vertebrae, namely the pedicular region of the posterior arch. In addition, they may occur in the subarticular bone within the confines of the synovial cavity, where they are termed intra-articular osteoid osteomas. Osteoid osteomas are most commonly located in the cortex of the bone, but they may be localized in the medullary cavity or periosteum of the bone. They are usually diaphyseal or metaphyseal, but on rare occasion they are epiphyseal.

The most common presenting symptom is a dull or sharp pain, usually worse at night, dramatically relieved by aspirin or other nonsteroidal anti-inflammatory drugs (NSAIDs). The duration of pain prior to presentation can vary from weeks to years. The second most common symptom is a limp. In lesions with relatively subcutaneous locations, such as the tarsal bones or phalanges of the hand, soft-tissue swelling may be present. Spine involvement may present as a painful scoliosis and unilateral muscle spasticity, with the concave part of the curve toward the side of the lesion (79). When the lesions occur near the physes, leg-length discrepancies may be observed with the affected extremity being longer. Other common signs on physical exam include muscle atrophy and structural (bowing) deformities.

The radiographic features of osteoid osteomas are highly characteristic and the diagnosis can often be made by plain roentgenograms alone. Conventional radiographs reveal a small, round radiolucent area within the cortex surrounded by a variable sclerotic zone (Fig. 127.14). The tumor may exhibit different stages of mineralization and therefore display different degrees of density. The reactive periosteal lamination may mimic Ewing's sarcoma. Epiphysiolysis often demonstrate a lack of sclerosis. Further imaging studies are indicated when typical plain film findings are not yet evident, when the exact location of the nidus is obscured because of extensive cortical thinning, when the lesion arises in an atypical location, or in anatomic sites that are difficult to image, such as the spine. The radionuclide bone scan is almost always positive for osteoid osteoma. Cross-sectional studies such as a computed tomography (CT) and magnetic resonance imaging (MRI) are especially helpful for areas that are difficult to image on plain films, such as the spine (Figs. 127.16, 127.17, and 127.18). CT appears to be a more accurate diagnostic tool than MRI because this modality displays the bony nidus and surrounding reactive bone in contrast to the normal cortex more clearly (7). The nidus is also less likely to be obscured by the edema associated with the lesion on CT scans than with MRI. It is important to get thin cuts through the area of a suspected nidus.

PREOPERATIVE MANAGEMENT AND PLANNING

The standard treatment for osteoid osteoma is en bloc resection of the nidus (65). Important aspects of the preoperative management include planning the most appropriate surgical approach, selecting a method for intraoperative localization of the nidus, and determining if a less invasive method is a reasonable alternative to wide excision. A CT scan is often useful in helping to plan the most direct operative approach. The method by which intraoperative localization of the nidus is to be
accomplished must be determined prior to surgery. Intraoperative bone scintigraphy, tetracycline labeling, CT guidance, and conventional radiography have all been used (85,155). Intraoperative nuclear scanning takes advantage of the lesion’s ability to concentrate radioscopy following preoperative administration. The area in question is sequentially scanned intraoperatively until activity is appreciably diminished (Fig. 127.1E) (85). This indicates that the lesion has been completely removed.

Similarly, tetracycline labeling also relies on the ability of the nidus to concentrate this compound. After oral administration 24–48 hours preoperatively, an ultraviolet lamp is used to demonstrate the presence of uptake in the resected specimen. Tetracycline labeling should be reserved for patients over the age of 8 years because of its affinity for developing dentin and associated tooth discoloration.

CT-guided placement of probes is helpful in localization of the nidus but does not quantitate the adequacy of resection. Plain radiographs can be used in conjunction with intraoperative markers for immediate postresection imaging of the host or specimen. The exact perioperative method to determine complete removal of the nidus is chosen based on the surgeon’s experience and the imaging modalities available.

For some patients, complete excision of the osteoid osteoma may require excessive bone resection, or it may not be possible because of anatomic considerations. Proper preoperative planning will identify those patients in whom a significant amount of bone must be removed to reach the lesion or to ensure adequate margins, and it will allow the surgeon to anticipate the need for bone grafting and internal fixation. Alternatively, a variety of percutaneous procedures for osteoid osteoma removal have been described. Percutaneous treatments have obvious advantages, including minimal invasiveness, relative safety, cost-effectiveness, and earlier return to normal activities. Bone trephination under CT guidance has been reported by several investigators with varying degrees of success (163). Percutaneous radiofrequency ablation has met with success and in a number of tumor centers and has become the procedure of choice in some institutions for lesions outside the spine (8,119,131). The technique involves introducing a radiofrequency probe over a biopsy needle, placed under CT control (Fig. 127.2). A 1 cm area containing the nidus is subjected to thermal necrosis after obtaining tissue for pathology. When comparing this approach to the more traditional open procedure, recurrence rates are essentially equivalent. The results from these percutaneous techniques appear encouraging.

Nonsurgical management of osteoid osteomas has been suggested by some authors (80). Their experience argues that there are circumstances in which operative treatment may cause complications and disability more severe than those associated with the original condition. The medical management of osteoid osteoma involves a prolonged course of NSAIDs. Patients treated successfully by this regimen were administered medication for an average of 33 months. Contraindications to medical management include drug hypersensitivity, progressive deformities, and uncertain diagnosis. While nonoperative management may have a role, the subset of patients in which this treatment plan is preferred has yet to be identified.

**OPERATIVE TECHNIQUE**

**En Bloc Resection**

The classic surgical procedure for osteoid osteoma is a marginal or wide excision. The goal of surgery is to remove the entire nidus, as incomplete excision is associated with high recurrence rates and persistent pain. The amount of the surrounding reactive bone that is removed varies: The intent is to leave as much bone as possible to reduce the risk of pathologic fracture. To limit the amount of bone removed, one of the intraoperative imaging modalities just described should be utilized. As mentioned, bone grafting and internal fixation may be required to restore adequate structural integrity. This is especially true of femoral and tibial diaphyseal lesions in which extensive cortex may need to be excised. Excise lesions about the femoral neck using a fracture table, or a radiolucent table to allow for fluoroscopic imaging and internal fixation if needed.

**Burr-Down Technique**

The burr-down technique was described to avoid the possible complications of an extensive excision, which weakens the bone and predisposes it to fracture and the morbidity associated with autogenous or allogeneic bone graft.

- After intraoperative localization, identify the reactive cortex visually by its characteristic elevation and roughening, and expose it subperiosteally.
- Use a high-speed burr or osteotomes in a successive sweeping motion over the reactive cortex until the nidus is encountered (164).
- Remove the nidus of tissue by curettage and submit it for histologic confirmation. Then burr the cavity in all directions for 1–2 mm and smooth the edges. Bone grafting is usually not necessary.

Postoperative management depends on the degree of resection. Wide excisions often require prolonged periods of immobilization, a longer hospital stay, and protected weight bearing. Patients treated by the burr-down technique reportedly require fewer activity restrictions. Percutaneous techniques are often performed as an outpatient procedure and may not require weight-bearing precautions.

**OSTEOBLASTOMA**

**CLINICAL AND RADIOGRAPHIC PRESENTATION**

Benign osteoblastoma is an uncommon benign bone-forming tumor accounting for less than 1% of all primary bone tumors. It has been called by some authors giant osteoid osteoma, and these two lesions are often histologically indistinguishable (44,76). The microscopic appearance is characterized by benign-appearing osteoblasts producing woven bone and osteoid in varying shapes and amounts. Despite their similar microscopic patterns, their respective growth potentials and hence clinical courses differ remarkably (78). Osteoid osteomas rarely exceed 1.5 cm, whereas osteoblastomas often exceed 2 cm. In addition, patients with osteoblastoma do not typically describe night pain, a hallmark feature of osteoid osteoma. Radiographically, osteoblastomas often lack the peripheral sclerosis seen with osteoid osteoma. Despite these differences, it may be difficult to distinguish between these two entities. In such instances, size greater than 1.5 cm has arbitrarily been chosen as the determining factor to make the diagnosis of benign osteoblastoma. Osteoblastoma typically presents during the second decade of life. Most patients are between the ages of 5 and 45. There is a male to female ratio of 3 to 1, which is similar for the sex distribution encountered in osteoid osteoma.

An entity referred to as aggressive osteoblastoma has been identified. These tumors are borderline lesions whose radiographic and histologic characteristics fall between benign osteoblastoma and osteosarcoma. Radiographically, aggressive osteoblastomas extend beyond the cortical margins of the bone, resembling an aneurysmal bone cyst. Microscopically, areas of epitheloid osteoblasts are present. Neither malignant transformation nor metastases of these lesions has been reported. However, these tumors are more likely to recur following incomplete or intralesional excision. The true incidence of this subset of osteoblastomas is not known.

The skeletal distribution for osteoblastoma is unique and distinguishes it from other benign bone lesions, including osteoid osteoma. Osteoblastoma has a predilection for the spine, particularly the posterior vertebral elements (84). In large series, up to a third of cases were located in the spine with near equal distributions in the cervical, thoracic, lumbar, and sacral spine (112). The second most frequent site of involvement is the long bones, followed by the bones of the hands and feet.
Pathologic fractures through the lesions have not been reported.

Clinically, pain is the most common presenting symptom. The pain increases in severity with time and has an unpredictable response to anti-inflammatory agents. Swelling and atrophy of the affected area may be present on physical exam. When the spine is involved, the patient often presents with a painful scoliosis and limitation of motion secondary to paraspinal muscular spasm. The lesion is usually located at the apex of the concavity of the curve. The scoliosis usually resolves following removal of the offending lesion. Persistent structural deformity may ensue if there is a significant delay in diagnosis. Neurologic deficit as the presenting complaint is not uncommon with spinal lesions. While the symptoms are typically mild, severe neurologic compromise has been reported.

Several radiographic studies may be used to evaluate osteoblastoma. Standard biplanar radiographs are typically capable of detecting lesions outside the sacrum. They reveal a round osteolytic lesion often greater than 2 cm in diameter, containing varying amounts of internal mineralization and surrounded by reactive bone. The lesions may be intramedullary, but the majority are intracortical. In addition, osteoblastomas may arise in the diaphysis, metaphysis, or epiphysis. When epiphyseal lesions do exist, they most often occur in the hands and feet. Details of spine lesions, such as the extent of mineralization and degree of rim sclerosis, are more easily discernible on CT scan. Spine lesions are often expansile, CT scan is superior to plain films in evaluating the relationship of the tumor to adjacent neurologic structures and for the purposes of staging and preoperative planning. If evidence of spinal cord or nerve root compression is apparent, obtain an MRI, as it provides exceptional imaging of the neural elements. Radionucleotide studies will demonstrate intense focal accumulation of the isotope. This study is perhaps most useful to help localize the origin of the lesion in patients with back pain in whom the diagnosis of osteoblastoma is suspected. Multicentric involvement has not been reported.

PREOPERATIVE MANAGEMENT AND PLANNING

As with other benign bone tumors, the threat of recurrence must be balanced against the complications associated with aggressive resections, given the nonmalignant nature of the lesion. Treatment of the osteoblastoma largely depends on its location and behavior. When possible, perform a complete or marginal excision. Recurrence following incomplete intralesional curettage occurs in up to 15%.

Margins can be extended using cryotherapy or phenol as described in the section on management of giant cell tumor.

The spine deserves special consideration, since the same treatment protocols for managing aggressive benign lesions in the extremities often are impractical given the anatomic restrictions and potential neurologic complications associated with spinal surgery. Such tumors may prove to be unresectable or even lethal in the spine. Employ the methodical approach to all spine neoplasms as described by Weinstein et al.

- Perform a complete clinical and imaging workup before biopsy.
- Decide the most appropriate medical and surgical treatments, as well as possible adjuncts depending on the patient's overall condition and tumor stage.
- Plan the surgery according to a standardized spinal surgical staging system.
- Make every effort to preserve neurologic function.
- Maintain spinal column stability. Treat osteoblastoma according to its oncologic staging. Stage 2 lesions can probably be managed adequately with intralesional curettage. Stage 3 lesions are best treated with marginal resection. When marginal resection is not feasible, adjuvant radiation therapy may have a role, although its efficacy has yet to be demonstrated.

OPERATIVE TECHNIQUE

In the extremities, do a complete excision when possible. When en bloc excision is not possible because of anatomic considerations, such as proximity to the physis, intralesional curettage is acceptable, especially for stage 1 and 2 lesions.

- Curet the tumor with conventional hand curettes, mechanically extending the margins to normal tissue with the use of a high-speed motorized burr.
- For aggressive osteoblastomas, some authors advocate the use of adjuvants such as cryotherapy and phenol. Use these agents judiciously as their complications have been well documented and experience in treating osteoblastomas is limited.
- Small defects can be filled with bone graft. Larger defects may require internal fixation to achieve adequate structural integrity.
- In the spine, intralesional curettage is often used, as complete excision is frequently not possible. In such cases, perform an extralesional dissection as far as possible.
- As these lesions are usually extremely vascular, ligate identifiable feeder vessels as they are encountered.
- Then remove the tumor in piecemeal fashion. Curet or burr the walls of the cavity. All of the peripheral sclerotic reaction need not be removed.
- Take care to preserve stability of the spine; internal fixation may be required.

GIANT CELL TUMOR

CLINICAL AND RADIOGRAPHIC PRESENTATION

Giant cell tumor (GCT) is a rare bone tumor accounting for only 4% to 5% of all primary bone tumors in the United States. In Southeast Asian regions, GCT accounts for approximately 20% of all primary bone tumors. The peak age of incidence is in the third decade of life, with 70% of the cases diagnosed in persons 20–40 years old. Although there have been numerous reports of GCT arising in patients with open growth plates, this presentation is the exception. When it occurs in children with open growth plates, the lesion is metaphyseal. In skeletally mature patients, it is found most often in the epiphyseal ends of long bones, especially the distal femur, proximal ulna, and distal radius. Approximately 60% of the cases occur about the knee. It is uni- or bicondylar, with or without extension across the joint line.

When it occurs in the spine, the vertebral body is most frequently involved. A slight female to male predominance exists. Multicentric involvement has been reported, but is rare.

The clinical presentation of GCT is consistent with its active and locally aggressive tendency to increase pressure within the bone or break through the cortex and stretch the periosteum. As such, the predominant presenting symptoms are pain and swelling of variable severity. In addition, patients may present with decreased joint range of motion or pathologic fracture. On physical exam, a tender, hard mass is typically found. The involved extremity may display muscle atrophy secondary to disuse, joint effusion, and elevated temperature of the overlying skin.

Radiographically, GCT appears as an eccentric, juxtaarticular, expanding zone of radiolucency at the ephiphysioendosteal end of a long bone. The tumor is a well-delineated lesion with irregular endosteal margins. There is usually no reactive bone at the periphery of the lesion. According to the staging system for benign bone tumors, the lesion most typically presents as an active (stage 2) or aggressive (stage 3) tumor. The tumor frequently extends to the subchondral bone of the articular surface and destroys the surrounding cortex, extending into the soft tissue. Because of the rapid expansion, a periosteal reaction is rarely seen. The combination of substantial destruction and poor margination may suggest malignancy.

![Figure 127.3](https://via.placeholder.com/150)

**Figure 127.3.** AP radiograph (A) of a giant cell tumor (GCT) of bone shows a radiolucent lesion of the lateral distal femur involving the epiphysis and the metaphysis. It has destroyed the cortex although the periosteum is intact, and it is well delineated although not well margined. In the lateral film (B), it is apparent that the lesion extends down to the subchondral bone distally and along the patellofemoral joint. This has the typical appearance of a GCT of bone. AP (C) and lateral (D) radiographs show the postoperative findings in this patient who was treated with extensive curettage, burring of the cavity, and packing with PMMA bone cement and reinforcing metal rods.
Although GCT is considered a benign neoplasm, a number of well-documented cases of pulmonary metastases have been reported in the literature (22,29). These so-called pulmonary implants are believed to occur in only 1% to 2% of patients with GCT. They are to be distinguished from true metastases secondary to malignant degeneration of GCT. Malignant degeneration of GCT is a phenomenon that usually occurs secondary to treatment of the original lesion, most typically radiation therapy (23). Pulmonary involvement in GCTs typically has a good prognosis, although up to 25% of patients die from the disease. Occasionally, the metastatic lesions may even spontaneously regress. The histology of the primary lesions of patients with pulmonary involvement (unlike that of patients without pulmonary involvement) fails to demonstrate any significant predilective features (29). In fact, histologic material from the lung is identical to that of the primary lesion. Chest radiographs should be obtained at regular intervals as part of the patient’s management. Early detection is important given the unpredictable nature of pulmonary lesions. Complete resection is recommended (29,78).

PREOPERATIVE MANAGEMENT AND PLANNING

Because of the aggressive nature of this lesion, establish a firm diagnosis. Malignant lesions must be ruled out by tissue biopsy prior to surgical treatment.

Giant cell tumors have a high potential for local recurrence. Adequate removal of the tumor leads to the lowest risk of recurrence (16). Aggressive resections, which may necessitate allograft or prosthetic reconstruction with their associated complications, must be weighed against the fact that GCT is almost always a benign neoplasm (125). Several methods for the treatment of GCT have been described and used with varying degrees of success: curettage alone, curettage combined with adjuvant therapies, en bloc resection, amputation, and radiation.

In general, an operative plan can be developed by considering three factors: (a) the type of resection, (b) the use of adjuvant therapy, and (c) the type of material to be used to fill the resultant defect. The first of these considerations involves deciding whether to do an intralesional or en bloc resection. Most GCTs are treated by intralesional curettage. The recurrence rate using curettage alone has been reported to be as high as 50%. The risk of local recurrence is greatly diminished by adjuvant therapies, en bloc resection, amputation, and radiation.

In general, an operative plan can be developed by considering three factors: (a) the type of resection, (b) the use of adjuvant therapy, and (c) the type of material to be used to fill the resultant defect. The first of these considerations involves deciding whether to do an intralesional or en bloc resection. Most GCTs are treated by intralesional curettage. The recurrence rate using curettage alone has been reported to be as high as 50%. The risk of local recurrence is greatly diminished by adjuvant therapies, en bloc resection, amputation, and radiation.

Use adjuvant therapy to eliminate microscopic disease following intralesional curettage. The most commonly used adjuvants alone or in combination are cryotherapy, phenol, and polymethylmethacrylate (PMMA). All have distinct advantages and disadvantages. Cryotherapy using liquid nitrogen has the ability to advance the resection margins because it creates a 1–2 cm zone of tissue necrosis (96). Complications of liquid nitrogen include fracture and local skin necrosis. Phenol also causes tumor cell necrosis, and reduced penetration results in only 1–2 mm of osteonecrosis, providing a theoretical advantage over liquid nitrogen by reduction of fracture rates. Phenol, however, can cause local chemical burns and exert systemic toxic effects on other organ systems. Both of these agents must be used with considerable caution. Their potential local toxicity can be difficult to control because of leakage. PMMA causes local necrosis in at least 2–3 mm of bone by its thermal effects during polymerization (107). A major advantage of PMMA is its immediate structural stability; also, radiographic detection of local recurrence is easier (15,114). The long-term risk of early degenerative changes in an adjacent joint secondary to the stiffness induced by subchondral PMMA, while yet to be substantiated, remains a concern.

After adequate removal of the tumor, fill the resultant cavity if the defect is of substantial size, which it will be in the majority of cases. The two most commonly used bone fillers for this purpose are PMMA and bone graft. The results of autogenous or allogenic bone graft, when used in conjunction with phenol or liquid nitrogen, appear to be comparable to cementation (125). The risks of donor-site morbidity for autogenous graft and the possibility of disease transmission for allogenic graft must be considered.

OPERATIVE TECHNIQUE

Intralesional Excision

Intralesional curettage is usually the treatment of choice and should be performed in systematic manner.

- After exposing the bone over the tumor, make a large cortical window the size of the longest longitudinal dimension of the tumor to provide adequate visualization of the entire tumor cavity (Fig. 127.4) (13). Make the window elliptical, with its axis parallel to the long axis of the bone to reduce the stress-riser effect. Incorporate an already thinned or destroyed area of cortex to minimize additional bone loss.

![Figure 127.4](image.png)

- Remove the soft-tissue portion of the tumor and thoroughly curet the walls, breaking down septae and getting into all the nooks and corners. Then thoroughly remove any residual tumor with a power burr.

- If the tumor extends into the soft tissues, excise the entire pseudocapsule. Take care to minimize contamination of surrounding tissues. Then thoroughly irrigate the cavity with pulsed lavage using saline.

Cryotherapy

- If cryotherapy is chosen as the adjuvant of choice, before the introduction of liquid nitrogen, identify any bony perforations and seal them to prevent damage to the surrounding soft tissues and neurovascular bundles.

- Use a tourniquet. This maximizes the freezing by minimizing heat exchange due to 2° blood flow.

- Use the direct pour technique described by Marcove (96). Place a stainless steel funnel in the bony defect, which is insulated with Gelfoam (Fig. 127.5). Pour liquid nitrogen (–196°C) through the funnel, filling the entire cavity.

![Figure 127.5](image.png)
Use a warm saline solution to irrigate the surrounding soft tissues to minimize thermal injury.

Leave the liquid nitrogen in the cavity until it evaporates completely, which typically takes 1–2 minutes followed by 3–5 minutes of spontaneous thawing. Repeat this freeze and thaw cycle 3 times. Some authors advocate the use of liquid nitrogen in a spray form, claiming better control over the chemical's dispersal. Irrigate the cavity with saline between cycles.

**Phenol**

Phenol exerts its cytotoxic effects by protein coagulation. It has the capacity to penetrate only 1 or 2 mm, behaving more like a surface agent.

- After thorough intralesional excision, apply phenol to the bony surface using cotton-tip applicators. Usually, a concentration of 12% to 50% phenol is used. Treat the entire surface, including crevices.
- Wash the cavity with alcohol to dissolve the phenol and minimize its local adverse effects. Follow with pulsatile lavage.
- Following adjuvant treatment, reconstruct the defect using bone graft, bone graft substitute, or PMMA (136). Pack PMMA from the articular surface outward (Fig. 127.4C, Fig. 127.3C, Fig. 127.6C). As the PMMA sets, use long, saline-soaked cotton-tipped applicators to insert the PMMA without thermal damage to the surrounding soft tissues. Use radiopaque cement to facilitate follow-up examinations for recurrence. Cryotherapy has not been used autogenous and/or allogenic bone graft may be used as an alternative to PMMA (16).

Depending on the size of the defect, internal fixation may be necessary to protect the bone until bone healing and remodeling occurs. Several standard internal fixation devices are available, including plates and screws, Steinmann pins, or flexible intramedullary devices. In one large, long-term series, fracture following cryosurgery occurred only in those patients whose construct was not augmented with internal fixation (83).

Recurrent GCTs can be very challenging to manage. They often arise in stage 2 or 3 lesions, or in anatomic sites that are difficult to treat aggressively. Small local recurrences can be treated with repeat curettage. More extensive local recurrence is probably best treated with wide excision, which often necessitates an extensive reconstructive procedure, such as arthrodesis or total joint replacement for a periarticular tumor.

**FIBROUS CORTICAL DEFECT AND NONOSSIFYING FIBROMA**

**CLINICAL AND RADIOGRAPHIC PRESENTATION**

Of the benign lesions within the bone, the fibrous cortical defect (FCD) and nonossifying fibroma (NOF) are common lesions in childhood, perhaps representing 5% of benign bone tumors (155). These benign conditions have many designations. The World Health Organization (WHO) prefers the term metaphyseal fibrous defect and describes the lesion as “a well-defined nonossesive bone lesion” containing “spindle-celled fibrous tissue with a storiform pattern and containing a variable number of multinucleated giant cells, hemosiderin pigment, and lipid-bearing histiocytes” (139). Nonossifying fibroma is probably the most commonly applied term, but lesions confined to the cortex are called fibrous cortical defects. The terms histiocytic xanthogranuloma, histiocytic fibroma, and nonosteogenic fibroma also have been used. The distinction between NOF and benign fibrous histiocytoma is subtle, and some pathologists use the terms interchangeably (11).

The etiology is unclear, but most authors consider it to be a nonossicence process probably of histiocytic origin (87,138). It may be a developmental defect or hamartoma, associated with a vascular disturbance or related to intraosseous hemorrhage. The relationship to the growth plate and metaphysis suggests an alteration in the remodeling process (12,128). The lesion is usually solitary, but it may involve multiple bones (177). Most often they slowly involute and fill in with host bone over time. Some may enlarge in the adolescent years (177).

Both NOF and FCD are located in the metaphysis of the long bones, especially the distal femur and the proximal and distal tibia, but they may also occur in the upper extremities (proximal humerus, distal radius, and ulna). They occur primarily in the first two decades and are rarely seen in adults. Boys are affected slightly more than girls (138,159). Caffey (21) found one or several of these lesions to be present in early childhood in skeletal surveys in 36% of individuals studied. Although occasionally persisting into adulthood, most of these lesions disappear soon after late adolescence and generally produce no symptoms unless a fracture occurs (5).

Their radiographic appearance is sufficiently characteristic to make biopsy unnecessary. They are oval, elongated, purely radiolucent areas that align themselves along the cortex of the metaphysis and metaphaladysis (Fig. 127.6A, Fig. 127.6B) (24,38). They are well marginated by host reactive bone and frequently exhibit bony septations. Ritsch et al. (128,129) observed that they are most frequently seen at sites of ligament, tendon, or intraosseous membrane attachment to the bone. The cortex may be thinned, but the periosteum is intact. However, axial imaging with CT or MRI may show areas of incomplete periosteal containment. By adulthood, the epiphysis has migrated away from the lesion and it appears as a dense osseous cortical scar or occasionally involves the medullary cavity (now called NOF). No metastases have ever been reported, and spontaneous regression of these lesions is the rule.

![Figure 127.6. AP (A) and lateral (B) radiographs of a typical nonossifying fibroma.](image)

The lesion is often an incidental finding following an injury to the ankle or knee in an otherwise asymptomatic child. It is seldom the cause of pain, although in rare instances an NOF may be painful for unknown reasons. In about 20% of the cases, the lesion presents as a pathologic fracture.

**PREOPERATIVE MANAGEMENT AND PLANNING**

The perplexing dilemma for the orthopedist is to decide whether the lesion is weakening the bone sufficiently to warrant surgical intervention. For patients who present without a fracture, decide whether or not to recommend surgical treatment. If left alone, these lesions will regress and heal, usually at about the time of skeletal maturity. In a young, athletically active child, however, the risk of fracture may be significant. It is difficult to convince the child to be careful for several years while the lesion heals.

We generally recommend curettage and bone grafting for lesions that appear to be significantly weakening the bone. Unfortunately, there are no clear guidelines to make this determination. One recommendation is to graft lesions that occupy more than half the diameter of the bone (5,21,122). However, other authors have observed low fracture rates in NOFs of the femur and tibia involving more than 50% of the long-bone diameter (49). More recently, CT scans obtained by a special protocol (5) and phantoms have been used. A biomechanical analysis of the CT data using the density of the involved bone and the thickness of the cortex compared to the uninvolved side yields a prediction of bone strength in various loading conditions (68,104). If the bone appears to be significantly weakened, we are more likely to recommend operation.

In the patient who presents with a fracture, we usually recommend allowing the fracture to heal with cast immobilization, followed by observation. In a fracture of a major long bone, such as the femur, internal fixation may be necessary initially. At times, the lesion will heal after fracture. If it does not, it seems prudent to curet and graft the lesion to prevent subsequent fracture.
OPERATIVE TECHNIQUE

Expose the bone overlying the lesion. The curettage does not have to be as aggressive as that for GCT, but the entire lesion should be curetted. It may be useful to complete the curettage with a high-speed burr.

For lesions of the femur or hip region, internal fixation and grafting of the fracture may be indicated. The choice of autograft or freeze-dried allograft to fill the defect is decided by the patient and treating physician (39, 120). Local recurrence is unusual.

UNICAMERAL (SIMPLE) BONE CYST

CLINICAL AND RADIOGRAPHIC PRESENTATION

The simple or unicameral bone cyst (UBC) is a lesion of unknown etiology that is common in the first two decades of life, primarily between the ages of 5 and 15 years. Boys are affected three times more commonly than girls (23, 138, 159). The cysts most commonly occur in the proximal humerus (50% to 60%) or proximal femur (25% to 30%) of a growing child, but other bones may be affected (23, 138). In older children and adults, cysts occur most commonly in the calcaneus or flat bones (147).

Bone cysts are asymptomatic unless there has been a fracture. They may occasionally be discovered by serendipity on radiographs obtained for other reasons. There is no mass or tenderness unless there is a fracture. There may be angulation of the limb secondary to the fracture, or shortening if the adjacent growth plate is involved. Occasionally, a cyst that has fractured will heal and disappear as the fracture heals, but this is the exception.

The lesion is not a true cyst because it is not lined by endothelial cells but rather by a thin fibrous lining of compressed fibrous tissue and blood vessels. The fluid is either serous fluid similar to extracellular fluid or blood filled if there has been a fracture (33). The cause is completely unknown (29). Many authors have proposed theories, but a definitive explanation has not been forthcoming. Some propose it to be either a disorder of the growth plate or a transient circulatory compromise resulting from a developmental anomaly of the veins of an affected bone (31, 33, 34, 67, 77, 138). The role of trauma has been postulated but not proven. Increased intraosseous pressure has been noted, and recently prostaglandins, free radicals, and other bone-resorbing factors have been noted in the fluid of the cyst (81, 82, 144). This may explain the success of steroid injection in the treatment of these lesions. The cysts may occasionally cross the growth plate and destroy it over time, which leads to shortening (19, 23, 26). In the humerus, this is not a major problem for function, but it may produce a cosmetic problem if it occurs early in childhood. Angular deformities are also rarely noted (105).

On radiographs, the cyst appears as a central, radiolucent lesion on the metaphyseal side of the growth plate of a long bone (Fig. 127.74). The bone is widened but usually not to more than the width of the epiphysial plate (88). The cortex is thinned but intact, and the lesion is usually well demarcated. The cavity is filled with a fluid similar to serum and extracellular fluid, which may be bloody if fracture has occurred. Some authors classify cysts as active when they are juxtaposed to the growth plate, and latent when the growth plate has migrated away from the cyst (23, 26, 110). Presumably latent cysts are more likely to heal following treatment. A “fallen fragment” sign may be present, indicating that the lesion is fluid filled rather than solid. This sign is seen when a fragment of cortical bone becomes dislodged and gravitates to the dependent portion of the unicameral bone cyst. It is seen in 10% to 20% of cysts and only in the presence of a fracture (89, 102, 128, 153).

Figure 127.7: A: A unicameral bone cyst of the left proximal humerus is purely radiolucent and thins the cortex. It is not wider than the width of the growth plate, although it extends up to it. There is a suggestion that it crosses the growth plate and enters the epiphysis, which is somewhat unusual. B: An MRI of this patient's humerus shows the fluid-filled nature of the lesion and clearly demonstrates that it crosses the growth plate. This patient developed a limb-length inequality despite treatment of the cyst with injections.

Other diagnostic tests are usually not required except in unusual locations such as the pelvis. In such locations, a CT scan or MRI can document the extent of the lesion and its cystic nature. The MRI shows low signal on T1- and high signal on T2-weighted scans (Fig. 127.7B) (28). It can be helpful in distinguishing unicameral cysts from aneurysmal cysts, GCT, fibrous dysplasia, and other benign lesions. Unless there has been a recent fracture, UBCs do not have fluid-fluid levels (23, 89). A bone scan usually shows uptake at the periphery of the lesion, and a cold central area.

PREOPERATIVE PLANNING AND MANAGEMENT

Treatment has traditionally consisted of curettage and bone grafting (111, 148, 149). Despite this aggressive approach, recurrence rates from 20% to 45% have been reported. Because of this, subtotal resection with grafting (with recurrence rates in the 10% range) has been advocated by some, but at the expense of a much larger operation (49, 53, 100). More recently, Scaglietti et al. (155, 156) in Italy proposed needle aspiration and instillation of methylprednisolone acetate into these cysts. Although multiple injections were often required, they reported success in more than 90% of their cases.

Although randomized comparisons of these techniques have not been performed, most reports have indicated that steroid injections are as successful as curettage, if not more so (19, 50). Injection is associated with the least morbidity, so operative treatment is reserved for those who do not respond to steroid injection. It usually requires several steroid injections to achieve healing of the cyst, and the mechanism of action of the steroid remains uncertain. One suggestion has been that the steroids reduce the levels of prostaglandins within the cyst fluid, thus retarding bone resorption (144). Campanacci et al. (23) compared the results of curettage and bone grafting with steroid injection in a large series of patients. They also defined radiographic criteria for complete and incomplete healing. Complete healing rates from curettage and grafting (46%) and steroid injection (42%) were comparable. Partial healing was noted in another 26%. Multiple injections led to complete healing in 50% and incomplete healing in another 25%. Repeat curettage in the surgically treated group was associated with a high recurrence rate. Risk of recurrence in the curettage group was related to the proximity of the growth plate; recurrence after steroid injection depended on the size of the cyst, contiguity with the growth plate, and the multilocular appearance of the cyst.

Recently, injections with bone marrow and demineralized bone gel have been reported to be successful in preliminary, unpublished reports (28). Other authors have employed high-porosity hydroxyapatite cubes (27, 72) or tricalcium phosphate to fill the cavities (4, 27), with variable success. Another approach has been to inject the cavities with a sclerosing agent similar to that used for soft-tissue hemangiomas (1). Calcaneal cysts appear to respond better to curettage and grafting than they do to steroid injection (59) and therefore are usually treated with surgery.

OPERATIVE TECHNIQUES

Curettage

- Use standard surgical approaches to expose the wall of the cyst in the involved bone (see Chapter 1, Chapter 2 and Chapter 3).
- Make a window in the bone and aspirate the fluid. Completely curet the lining tissue, taking care to prevent injury to the growth plate. Then pack the lesion with autograft or allograft bone chips or other bone graft substitutes.

Injection
Aneurysmal bone cysts can be treated by curettage, marginal excision, or, rarely, wide excision. In bones deemed expendable, such as ribs or the fibula, wide excision is preferred. Arterial embolization can be done using polyvinyl-alcohol particles.

**OPERATIVE TECHNIQUE**

Infusion tests with amobarbital sodium, with the patient awake, or using somatosensory evoked potential monitoring (SEP) may be used to assess neural compromise, or reconstruction would be technically dangerous. Both radiation and arterial embolization have been used with success in these instances. While radiation may play an important role in the etiology of UBCs, and drilling may decrease the intracystic pressure, embolization is the preferred method.

Another technique is to drill multiple holes in the cyst, and in some instances to leave wires in place, to allow continued drainage. The successful results suggest that venous obstruction may play an important role in the etiology of UBCs, and drilling may decrease the intracystic pressure. We have no experience with this technique. It is not yet used much in North America.

### ANEURYSMAL BONE CYST

An aneurysmal bone cyst (ABC) is a benign vascular tumor-like condition of unknown origin that accounts for approximately 1.5% of primary bone tumors (141). It is a multiloculated, radiolucent, eccentric lesion that expands the bone, giving it a “blown-out” appearance. Historologically, it shows mesenchymal tissue-lined cysts containing blood. ABCs are believed to be reactive lesions caused by some hemodynamic disturbance in the rich capillary network of the host bone resulting in an expansive destructive process. This hypothesis was based on the observation that intracystic manometric pressure measurements were similar to arterial pressure (14).

Controversy exists as to whether ABCs are truly a distinct pathologic entity or a secondary phenomenon superimposed on a preexisting lesion (83). In up to 50% of cases, a preexisting lesion can be identified. The most common of these is GCT, followed by osteoblastoma and chondroblastoma (99). Other underlying lesions include fibrous dysplasia, NOF, chondromyxoid fibroma, solitary bone cyst, eosinophilic granuloma, osteosarcoma, fibrosarcoma, and metastatic carcinoma. Although the lesion is benign, it is locally destructive with a high propensity for recurrence. The reactive lesion can also be solid in the form of a giant cell reparative granuloma, and then it is called a solid ABC (134). ABC is diagnosed by exclusion, as many tumors both benign and malignant can have a similar clinical and radiographic presentation.

### CLINICAL AND RADIOGRAPHIC PRESENTATION

Primary ABCs typically occur in the second decade of life. They have been reported to arise in almost every bone of both the axial and the appendicular skeleton, most often about the knee and in the vertebral column. Patients complain of pain and swelling of variable duration (weeks to years). Occasionally, a palpable mass may be identified. In the spine, compression may cause radicular symptoms, neurologic deficits, or even paraplegia. Patients may present with a pathologic fracture through the cyst, but this is uncommon given the eccentric nature of the lesion.

Aneurysmal bone cysts most often present as stage 2 or stage 3 disease. The radiographic appearance of an ABC is quite distinctive and almost diagnostic (Eq. 127.84). The characteristic features include a subperiosteal lytic expansile lesion inflating and thinning the cortex. In the early stages, periosteal reaction is scarce, giving the appearance of a malignant tumor. The lesion typically involves the metaphysis, and occasionally the epiphysis, and it may even cross the physis. Because the periosteal response may extend along the shaft of the bone beyond the lesion, it may have the appearance of a finger in a balloon. Most often the lesion is eccentric, but it can be central. In the spine, the lesion typically involves the posterior elements but may expand to involve the vertebral body as well as adjacent vertebral bone. CT and MRI are useful imaging modalities, especially in the axial skeleton. They are particularly helpful in confirming the diagnosis by demonstrating the characteristic fluid levels within the cyst (Eq. 127.85). It should be stressed, however, that the presence of these fluid–fluid levels is not pathognomonic for ABC. Other lesions, including GCT, unicameral bone cyst with fracture, and osteosarcoma, may have this finding.

**Figure 127.8 A:** AP radiograph of an aneurysmal bone cyst (ABC) shows an expanded radiolucent lesion in the metaphysis of the right distal tibia. The periosteum is intact and well marginated. There are some internal septations within the lesion. **B:** An MRI of this lesion shows the classic fluid–fluid levels. This was biopsied and proved to be an ABC.

### PREOPERATIVE PLANNING AND MANAGEMENT

The treatment of ABCs is surgical. Several details of the management must be carefully considered prior to surgery. Although the diagnosis of ABC can usually be made based on the imaging and clinical findings, malignant conditions, namely telangiectatic osteosarcoma, may mimic an ABC. As such, the initial surgical approach must take into account the possibility of encountering a malignant tumor and the need to perform a future limb-sparing procedure (see Chapter 129). Because of the vascular nature of the lesion, a large blood loss should be anticipated. Use tourniquets when possible and plan for blood replacement. In addition, certain lesions may benefit from preoperative selective arterial embolization. The extent of bony destruction must be fully appreciated prior to resection to restore adequate bony stability with or without internal fixation. Because the majority of these cysts arise in skeletally immature individuals, the proximity of the physis must also be fully appreciated to prevent premature growth arrest.

Finally, plan to have the various adjuvants available to be used in conjunction with intralesional excisions (curettage) as discussed for GCTs. ABCs have a high incidence of recurrence after incomplete excision. The recurrence rates after curettage alone have been reported to be from 20% to 59% (14). Numerous investigators have used bone graft, PMMA, or cryotherapy (alone or in conjunction with bone grafting or PMMA) in an effort to reduce the rate of recurrence (85,115,140).

Special considerations in the management of spinal ABCs include difficult accessibility, intraoperative bleeding, proximity of the spinal cord and roots, necessity of removing the entire lesion to prevent recurrence, and potential bony instability (119). The posterior elements are usually involved, and the majority of these lesions extend into the vertebral body. An axial imaging study such as CT or MRI is essential in the preoperative evaluation of spinal lesions. Most spinal ABCs can be treated through a posterior approach. Some extensive lesions may require an anterior or combined anterior and posterior approach (see Chapter 151 and Chapter 152).

There are instances in which a spinal ABC may not be amenable to surgery, such as when the extent of involvement is so great that excision or curettage would risk neurologic compromise, or reconstruction would be technically dangerous. Both radiation and arterial embolization have been used with success in these instances. While radiation has demonstrated efficacy, it is used infrequently because of the concern for secondary radiation-induced sarcoma (145). Arterial embolization was first explained as a definitive treatment by decreasing vascularity and hence intraoperative blood loss. However, its usefulness as a definitive treatment method has been demonstrated (42,43). Because spinal cord ischemia is a potential complication after arterial embolization, perform angiography followed by a provocative arterial infusion test with amobarbital sodium, with the patient awake or using somatosensory evoked potential monitoring (118). If no adverse changes are observed, selective arterial embolization can be done using polyvinyl-alcohol particles.

### OPERATIVE TECHNIQUE

Aneurysmal bone cysts can be treated by curettage, marginal excision, or, rarely, wide excision. In bones deemed expendable, such as ribs or the fibula, wide excision...
is recommended. While marginal excision has been performed with low recurrence rates, it is difficult to justify aggressive bone resection given that ABCs is a nonepithelial lesion with the potential for spontaneous healing and complete recovery after incomplete excision (141). The most common method for treating ABCs is aggressive curettage followed by reconstruction of the tumor cavity with bone graft or PMMA.

- Expose the lesion under tourniquet control whenever possible. Create a wide window by removal of part of the expanded cortical shell. Send a biopsy specimen for frozen section to confirm the diagnosis.
- Remove the cyst by thorough curettage until all fibrous tissue has been excised. The cessation of bleeding usually indicates that the lesion has been completely excised. The margins of the excision may be further extended using a motorized bur or a chemical adjuvant. Then assess the extent of the cavitary defect and choose an appropriate method of reconstruction. Cancellous bone grafting is preferred over PMMA for pediatric patients and small contained defects.

OSTEochondroma

CLINICAL AND RADIOGRAPHIC PRESENTATION

Osteochondroma, or osseocartilaginous exostosis, is by far the most common benign tumor of bone, accounting for 35% to 50% of benign bone neoplasms and 10% to 15% of all primary bone tumors (69). The actual incidence is probably much higher, as most lesions are asymptomatic and never discovered. They may occur as solitary lesions or much less commonly as multiple hereditary exostoses (MHE), which is most often inherited as an autosomal dominant trait although it can also occur sporadically. MHE lesions show significant variability in size, number, and distribution.

Osteochondromas are not true neoplasms but rather a developmental enchondromatous hyperplasia resulting in the formation of a cartilage-capped bony protrusion on the surface of a bone. They may occur in any bone that develops by enchondral ossification, most often in the distal femur, proximal tibia, and proximal humerus. In the axial skeleton, they most commonly arise in the ilium. There is a male to female predominance of up to 2 to 1, with most during the second and third decades of life.

An osteochondroma that continues to grow after skeletal maturity should raise the suspicion of malignant transformation. Malignant transformation almost never occurs in childhood. In adults, consider malignant transformation of the cap when there is such growth, and when the patient reports pain, especially in the setting of MHE. The malignancy associated with osteochondromas is most often chondrosarcoma, although malignant fibrous histiocytoma and osteosarcoma have been reported (52,113,172). It is estimated that the rate of sarcomatous change is approximately 1% per osteochondroma, although it is probably less. Central lesions (pelvis, scapula, ribs, spine) are at greatest risk for malignant transformation. Chondrosarcomas arising from osteochondromas have a better prognosis than other chondrosarcomas and rarely metastasize.

Patients usually complain of a hard, painless lump of long duration on the involved bone. Pain may be present resulting from impingement on or tethering of neighboring structures such as a tendon, muscle, or nerve. Pain may also arise from overlying bursal inflammation or a fracture through the stalk of the osteochondroma. On physical examination, a palpable mass is usually the only finding. Angular deformities or limb-length discrepancies may be present. Juxta-articular lesions may cause limitations of joint motion. Spine lesions may give rise to a variety of neurologic signs and symptoms secondary to cord or root compression (2,143). The most frequent sign of sarcomatous transformation is a sudden enlargement of a preexisting lesion in an adult. Pain is also a common, worrisome finding in these patients.

Radiographically, osteochondromas can be sessile or pedunculated (Fig. 127.9A,B). The roentgenographic picture of a pedunculated osteochondroma is so characteristic that it is virtually pathognomonic. A pedunculated lesion typically arises from the metaphysis of a long bone, with a stalk that is continuous with the adjacent cortex and is oriented away from the epiphysis. Sessile lesions demonstrate a flat, plateau-like protuberance, and have a wider differential diagnostic. The outline of the lesion is usually well demarcated, but it can vary from smooth to irregular. Prominent cartilaginous caps produce surrounding areas of calcification. CT and MRI are excellent imaging modalities to evaluate any questionable lesion, as they very nicely establish continuity with the cortex and underlying spongiosa of the host bone (Fig. 127.9C,D) (57). This is an important finding to document, especially in sessile osteochondromas that may be mistaken for parosteal osteosarcomas.

When considering chondrosarcomatous degeneration, suspicious radiographic signs include loss of a distinctive bony margin, an adjacent soft-tissue mass, and areas of variable mineralization within the lesion. Histologically, a cartilaginous cap larger than 1.5 cm in an adult is considered suspicious, although there is no absolute thickness specific for malignancy (52). While MRI and ultrasound have comparable detection rates and measurement accuracies for cap thickness determinations, MRI has the added ability to evaluate the surrounding soft tissues (94).
When malignant change is suspected, obtain adequate imaging studies, such as those previously mentioned, to fully appreciate the extent of the lesion. Treat these patients as you would those with conventional chondrosarcoma, including staging studies (151). A wide excision is the treatment of choice. Biopsy is usually not performed preoperatively, as the risk of seeding the biopsy track outweighs the possibility of obtaining a representative specimen, considering that low-grade cartilage lesions are difficult to interpret histologically. Most (85% in one series) of these secondary lesions are grade 1 chondrosarcomas (see Chapter 129).

For patients with MHE, corrective osteotomies are sometimes necessary to address functional impairment, angular deformities, and limb-length inequality (121). The three most common locations for involvement are the forearm, the ankle, and the knee. The most common of these is forearm deformity, resulting in ulnar deviation of the wrist associated with relative ulna shortening, bowing of both the ulna and the radius, and late dislocation of the radial head (17). These deformities usually progress, leading to functional impairment and cosmetic deformity. While a discussion of the exact surgical techniques to correct these complex malalignments is out of the scope of this chapter, it is worth mentioning that recognition and intervention may prevent it from worsening and reduce disability. Structural ankle valgus and genu valgum are not uncommon and benefit from corrective measures such as hemiepiphyseal stapling (see Chapter 165, Chapter 169, and Chapter 190).

OPERATIVE TECHNIQUE

When surgical intervention is elected, the most common procedure performed is excision of the osteochondroma. Osteochondromas are nearly always cured by complete excision. It is important to remove the entire cartilaginous cap and overlying perichondrium (137). Be careful not to violate the cartilaginous cap, as cutting into it increases the rate of local recurrence. Remove the tumor flush with the underlying bone. Incomplete excision of these elements is associated with recurrence, although for benign lesions in adults this rate is about 2%.

Complete removal of sessile lesions poses a greater challenge. Fortunately, these lesions tend to cause fewer symptoms necessitating surgery. For these lesions, it may occasionally be necessary to leave behind part of the cortical stalk to avoid compromising bony stability or the need to bone graft. Be certain to remove the cartilage cap at the exostosis–host bone junction.

The management of fractured osteochondromas is somewhat controversial (41). The majority of fractures through osteochondromas will heal with activity restriction. Painful fibrous nonunions, particularly about the knee, do occur. In such instances, the osteocartilaginous loose body can be excised, usually without incident.

Excise enlarging osteochondromas in adults because of the possibility of sarcomatous degeneration. Use the surgical principles for managing primary bone sarcomas (Chapter 128), performing resection with a wide margin to minimize the risk of local recurrence. In one large series from the Mayo clinic, intralesional excision led to a 78% recurrence rate compared to only 15% in those who underwent wide resection (52). For patients with low-grade (grade 1) chondrosarcoma, wide resection is almost always curative. Those with higher grades are at much higher risk for local recurrence and distant metastasis. All patients, regardless of grade, require lifelong surveillance. For patients with MHE, although they are at higher risk for malignant transformation than patients with solitary lesions, the same criteria for excision apply.

CHONDROBLASTOMA

CLINICAL AND RADIOGRAPHIC PRESENTATION

Chondroblastomas are primary tumors of bone that account for less than 1% of all primary bone tumors. They are composed of immature cartilage, multicellular giant cells, and areas of thin calcifications with a “chicken wire” pattern. These tumors classically arise in the epiphysis of a long bone, although they can appear in any secondary center of ossification. Typical sites include the distal femur, proximal humerus, and proximal tibia in tubular bones, and the acetabulum and iliac crest in flat bones. There is a slight male to female predominance. The majority of patients are in their second decade of life at presentation. Although the lesion most commonly presents in individuals with an open physe, tumors have occurred in skeletally mature patients. Chondroblastoma is one of the few benign bone tumors that has the potential to develop pulmonary metastases (152,153). The pulmonary nodules have the same histologic characteristics as the primary lesion, without evidence of malignant differentiation.

As with other benign bone lesions, the presenting symptoms can be nonspecific. The majority of patients describe pain in the affected extremity, usually of several months duration. The pain at times may be quite severe and sharp, similar to that of osteoid osteoma. Patients may also complain of swelling, joint stiffness, and limp. On physical examination, approximately 50% of patients will have tenderness to palpation over the lesion. Occasionally, a palpable inflammatory mass will be found, raising the suspicion of a malignant tumor. Decreased range of motion of the involved joint and muscle wasting are also common. The lesion rarely presents with a pathologic fracture.

On plain radiographs, the lesion is typically an eccentric, round, radiolucent lesion contained within the epiphysis (Fig. 127.10A,B). Chondroblastomas commonly cross the physe and extend into the metaphysis. Rarely is the lesion purely metaphyseal. The lesion may also arise in an apophysis. A well-demarcated rim of sclerosis surrounds the lytic area. Areas of calcification scattered throughout the lesion are present in approximately one third. When these intrinsic calcifications are not present on conventional radiographs, a CT scan may confirm their presence, lending support to the diagnosis of chondroblastoma. CT scans or MRI images are also of assistance in determining the exact proximity of the tumor to the physe and articular surface. An MRI will demonstrate the surrounding inflammatory host response to the lesion (Fig. 127.10C,D). Some chondroblastomas may exhibit an aggressive radiographic appearance with erosion or even expansion of the adjacent cortex. Histologically, these aggressive lesions often contain an ABC component. Secondary ABC is found in approximately 15% to 20% of chondroblastomas.

Figure 127.10. AP (A) and lateral (B) radiographs of the right knee show a radiolucent lesion in the lateral tibial epiphysis, which extends from the growth plate to the subchondral bone. In this case, there is no stippled calcification, but this location is typical for a chondroblastoma in this age group, and biopsy confirmed this. Frontal plate (C) and cross-sectional (D) MRI images nicely delineate the extent of this lesion within the epiphysis. On the frontal plate image, surrounding edema of the epiphysis is evident. In the axial image, there is a central dark area that represents mineralization within the lesion.

PREOPERATIVE MANAGEMENT AND PLANNING

Intralesional treatment of chondroblastoma is usually curative and the prognosis good. The standard treatment is biopsy followed by curettage and bone grafting. With this method, approximately 10% will recur within the bone or adjacent soft tissue, although up to a 20% recurrence rate has been reported (71,150). Biopsy is an important part of the treatment plan. While the differential diagnosis of epiphyseal lesions in childhood and early adulthood is somewhat limited (osteoeylitis and histiocytosis in rare instances), osteosarcoma may originate in the epiphysis (epiphyseal osteosarcoma) (158). In the adult, GCT, which is more accurately described as epiphyseal osteosarcoma, is more likely; less frequently is clear-cell chondrosarcoma seen. Clear-cell chondrosarcoma presents as an epiphyseal lesion and looks very similar to a chondroblastoma. The misdiagnosis of chondroblastoma in these instances would clearly result in inadequate treatment. In general, tumors involving the epiphysis in adolescents are usually chondroblastomas, whereas in the adult, GCT is more likely.

Perhaps the most important aspect of planning the surgical procedure is appreciating the close proximity of the tumor to the physe and articular cartilage. It is important to avoid entering the adjacent joint, as synovial membrane and articular recurrences may follow transarticular spillage of the tumor. Most authors agree that if the physe cannot be spared without compromising the margins of resection, it should be sacrificed, as overly conservative curettage is an invitation for tumor recurrence (71). Most of the time, the child is near skeletal maturity so that growth considerations are of lesser importance.
In the pelvis, we advise en bloc resection. For aggressive lesions, consider adjuvant therapy with phenol or liquid nitrogen to minimize recurrence. Finally, decide if autogenous or allogenic bone is necessary to fill the defect. Consider the morbidity of harvesting autograft as compared to the risk of disease transmission with allograft (59). For small defects, autograft and allograft have similar healing rates. For larger defects, autograft displays superior rates and completeness of healing. This increased efficacy presumes that an adequate amount of autogenous bone is available. Freeze-dried allograft bone is safe and generally works quite well. While chondroblastoma is relatively radiosensitive, radiotherapy is contraindicated because of the average patient's age and the risk of secondary sarcoma. Irradiation of skeletally immature bones leads to a reduction in bone growth, abnormal bone remodeling, and increased propensity to fracture (85).

**OPERATIVE TECHNIQUE**

In most cases, intralosional curettage will be the treatment of choice (56). When possible, perform curettage in an extra-articular manner. For most long-bone locations, standard surgical approaches can be utilized. Intraoperative fluoroscopy is extremely helpful. Bone graft the resultant cavity defect. Avoid subchondral PMMA in children, as its long-term effects on articular cartilage have yet to be determined. For lesions not directly adjacent to subchondral bone, PMMA has been used with success. In instances where the tumor has eroded through the articular surface, reconstruction of the joint surfaces with an osteoarticular allograft may be necessary. Recurrent lesions are probably best treated by wide excision when possible.

The proximal femur is not an uncommon location for chondroblastoma and presents unique considerations. While this lesion has historically been treated by anterior capsulotomy, an extra-articular approach has been described (152).

- With the patient on a radiolucent or fracture table, make a lateral approach to the greater trochanter.
- Under fluoroscopic guidance, introduce a guide wire from the lateral femoral cortex, through the femoral neck, into the center of the lesion in the epiphysis.
- Using a coring device or cannulated drill, drill a tunnel of sufficient diameter (approximately 1 cm) into the tumor.
- Remove the tumor with long curettes with narrow shanks and pituitary rongeurs.
- Under fluoroscopic guidance, introduce a guide wire from the lateral femoral cortex, through the femoral neck, into the center of the lesion in the epiphysis.
- After thorough curettage, pack the cavity with bone graft and replace the original autograft core back into the metaphyseal window if possible. Prevention of fracture can be achieved with interval fixation or spica case immobilization.

**CHONDROMA**

**CLINICAL AND RADIOGRAPHIC PRESENTATION**

Chondromas and enchondromatosis with the additional component of hemangiomas. Both are nonheritable diseases in which proliferating masses of benign cartilage afflict the bones formed by enchondral ossification. These diseases tend to affect men twice as often as women and are evident in childhood. The hands are most commonly affected. Enchondromas may be polyostotic in associated syndromes. Ollier's disease is characterized by multiple skeletal enchondromatoses. Maffucci's syndrome is multiple enchondromatosis with the additional component of hemangiomas. Both are nonheritable diseases in which proliferating masses of benign cartilage afflict the bones formed by enchondral ossification. These diseases tend to affect men twice as often as women and are evident in childhood. The hands are most commonly affected. Secondary chondrosarcoma is more common in both Ollier's and Maffucci's syndrome. It has been estimated that approximately 25% of patients with Ollier's disease will develop secondary chondrosarcoma, although this figure may be an overestimation reflecting a bias of those patients presenting to a cancer center. It is estimated that the incidence of malignant transformation of enchondromas in Maffucci's syndrome is higher, but the true incidence is unknown because many of these patients die from complications related to other malignancies (109).

Most typical solitary enchondromas are asymptomatic and are found incidentally as part of the workup for another condition or coincidental local trauma. Patients may present with pain or fracture through a weakened area of a longstanding tumor. Lesions in the proximal humerus are often detected when the patient is being evaluated for rotator cuff tears or tendinitis. This presents the difficult dilemma of determining whether the symptoms are due to malignant degeneration of the cartilage tumor or some other traumatic or inflammatory cause. Distal phalanx lesions may lead to ruptures of the flexor digitorum profundus tendon. Occasionally, painless swelling of a digit may be the chief complaint. Few patients will complain of pain related to the enchondroma in the absence of fracture. Pain in the lesion that is sharp, immediate, and severe following some type of strenuous or athletic activity is most likely a stress fracture through the enchondroma. Pain referable to the lesion that is vague and of longer duration is more likely to be associated with chondrosarcoma. Although chronic pain is thought to be an important aspect of the clinical history when assessing a patient for secondary chondrosarcoma, up to 50% of patients with biopsy-proven chondrosarcoma did not complain of pain (89).

Juxtacortical chondromas present with pain and overlying swelling and often a palpable mass. The pain is usually described as dull and aching, and it varies in duration from weeks to years. The swelling tends to be localized and may gradually increase with time. More frequently, these lesions are completely asymptomatic and especially in children can be followed with periodic radiographic evaluation (63).

In Ollier's disease and Maffucci's syndrome, clinical manifestations include gradual enlargement of the fingers, bowing deformities, shortening of the extremities, and limitations of tendon excursion. Patients with Maffucci's syndrome also present with subcutaneous hemangiomas. The phenotypic penetrance of these two entities is variable, with mild forms not detected until early adulthood and severe forms obvious in the first year of life.

The radiographic appearance of an enchondroma is usually that of a centrally placed, lucent lesion within the metaphysis or diaphysis, with mild forms not detected until early adulthood and severe forms obvious in the first year of life. The radiographic appearance of an enchondroma is usually that of a centrally placed, lucent lesion within the metaphysis or diaphysis of the bone. Thinning or scalloping of the cortex may occur, but there is usually a moderate amount of radiodense margin may occur, buld or sloped calcification is a frequent finding in adults (Fig. 127.11, Fig. 127.12). Some lesions may show well-circumscribed areas of relative radiolucency, with scattered amorphic calcifications centrally located in the medullary cavity of the bone. This picture is common for an enchondroma in the phalanges. Other lesions, such as those in the long bones, show large granular or flocculent collections of calcifications, with variable cortical thickening. Fractures through the thin cortices of the lesions in phalanges may be evident. Most lesions show an increased uptake on bone scans.

**Figure 127.11.** A: Radiograph of the distal femur of a 30-year-old woman with an incidental finding of an enchondroma of the distal femur. Note the typical “popcorn”
type of calcification with small rings and arcs. There is no evidence of cortical erosion. B: The CT scan from this patient confirms these findings. The cortex is intact and the mineralization of this lesion in arcs and amorphous rings is readily apparent within the medullary cavity.

Figure 127.12. A typical enchondroma in the proximal phalanx of the thumb of a 20-year-old man. It has enlarged the bone slightly, although the cortex is intact. There has been no mineralization, but the enchondroma has a characteristic appearance.

Juxtacortical (periosteal) chondromas present as a juxtacortical radiolucent mass, surrounded by peripheral periosteal host reaction at its base (Fig. 127.13). The base of the lesion is framed by a layer of cortical reactive bone and usually does not extend into the medullary cavity. There may be areas of stippled calcifications throughout the cartilaginous portion of the lesion.

Figure 127.13. A: AP radiograph of an 11-year-old boy shows a surface lesion of the right proximal humerus. Note “dish shaped” appearance and some periosteal elevation. B: MRI of this patient more clearly shows a cartilaginous mass sitting on the cortex of the bone. Unlike in osteochondroma, there is no communication of the medullary cavity with the lesion.

The radiographic appearance of Ollier’s disease and Maffucci’s is characteristic (Fig. 127.14). The multiple enchondromas are expansive and bubbly. The cortical margins are substantially thinned and may even be absent. The degree of calcification is variable. In the long bones, the remodeling deformities are manifested by bowing, shortening, and metaphyseal widening.

Figure 127.14. AP radiograph of the hands shows findings characteristic of a patient with Ollier’s disease. Multiple enchondromas can be seen in the phalanges and metacarpals of the hands, with gross distortion of the bones and enlargement of portions of many of the bones. Also typical is the relative increase in severity of the disease on this patient’s left hand compared to his right.

PREOPERATIVE MANAGEMENT AND PLANNING

Asymptomatic enchondromas can be observed. In the adult, follow these lesions with serial radiographs and CT to monitor changes in size and cortical destruction if the possibility of malignant change is a concern. The frequency of radiographic evaluation, which is necessary, has not been firmly established. We recommend that lesions that have characteristics associated with higher rates of chondrosarcoma, such as those in the axial skeleton, those larger than 5 cm, and those that involve more than 90% of the medullary cavity as visualized on axial tomography, be reevaluated every 6 months (35,54). Smaller, more peripherally localized lesions can be followed yearly or biannually.

Perhaps the greatest challenge in managing these tumors is distinguishing between benign enchondroma and low-grade chondrosarcoma. There are no clear-cut ways to do this radiographically, and even after histologic evaluation the distinction may be difficult. Signs indicating possible malignancy include new pain, soft-tissue mass, increase in size, cortical destruction, periosteal reaction, an area of radiolucency within a previous area of calcification, and marked increase in activity on bone scan (66,151). CT is a useful imaging modality for evaluating cortical scalloping, periosteal reaction, and soft-tissue mass (66). We feel that all adult patients with an enchondroma in a bone outside the hand should have a baseline CT scan or MRI.

OPERATIVE TECHNIQUE

- Expose the lesion through standard approaches. Treatment is principally by curettage and packing the defect with autogenous or allograft bone.
- If you are concerned about malignancy, use recommended techniques for primary bone malignancies (see Chapter 126). Make a direct and limited approach, allowing for a wide resection of the tumor should it prove to be malignant. Make a small window in the cortex to obtain tissue for diagnosis.
- Obtain tissue for a frozen section. If there is doubt about the diagnosis, obtain enough to avoid a sampling error—and wait for a permanent section diagnosis before definitive treatment. It is advisable to plug the biopsy defect with PMMA to prevent the spread of hematoma and tumor cells.
- For lesions that are clearly benign, make a window in the cortex, outlining it with multiple drill holes and an osteotome or a high-speed burr (Fig. 127.15). Do a complete curettage to ensure complete removal. Submit all removed tissue for histologic examination to rule out low-grade chondrosarcoma.
look promising as an effective and well-tolerated treatment (reduce bone turnover, and improve the radiographic appearance in one series of patients with fibrous dysplasia. While these data are preliminary, bisphosphonates

Nonsurgical management of fibrous dysplasia using bisphosphonates is currently under investigation. Intravenous pamidronate has been shown to alleviate bone pain, has received irradiation. Do not irradiate the bone lesions of fibrous dysplasia.

Malignant degeneration is extremely rare, occurring in 0.5% to 1% (stature secondary to premature physeal closure is common. Short lesions are flat and light to dark brown; sometimes, extensive areas of pigmentation with irregular margins present as café-au-lait lesions. Precocious puberty is the most common endocrinopathy, but acromegaly, hyperparathyroidism, vitamin D–resistant rickets, hyperthyroidism, and Cushing's syndrome may be present. Short stature secondary to premature physeal closure is common.

Radiographically, the lesions of fibrous dysplasia have a lucent or “ground glass” appearance and cause thinning of the cortex and endosteal scalloping (Fig. 127.16). The bone may be enlarged or deformed (e.g., “shepherd's crook” deformity of the proximal femur), and it may be involved from one end to the other (Fig. 127.17). Tiny purposeless trabeculae are noted within the lesion.

FIBROUS DYSPLASIA

Fibrous dysplasia is a disorder of fibro-osseous tissue that more likely represents a developmental abnormality of bone than a true neoplasm. No consistent familial or hereditary factors have been identified, but recently, activating missense mutations of the Gs alpha gene leading to overactivity of adenylyl cyclase have been identified in patients with McCune-Albright syndrome (127). This mutation can result in independent cell proliferation. The mutation in this syndrome is a missense point mutation in exon 8 that results in the substitution of histidine or cysteine for arginine at position 201. Recently, four cases of monostotic fibrous dysplasia were demonstrated to have such a missense mutation, whereas other fibrous lesions and uninvolved tissue did not contain a mutation (3). The presence of somatic activating mutations of Gs may differentiate fibrous dysplasia from the other lesions and may be responsible for the loss of control of local proliferation and growth factor expression. Increased expression of the c-fos proto-oncogene has recently been noted in patients with McCune-Albright syndrome and may also be important in the pathogenesis of the bone lesions in patients with fibrous dysplasia (25).

CLINICAL AND RADIOGRAPHIC PRESENTATION

The diagnosis can often be made in childhood, but recognition may not occur until adult life. Three clinical syndromes exist: monostotic fibrous dysplasia, polyostotic fibrous dysplasia, and McCune-Albright syndrome (61). The monostotic form occurs at any age, with the second and third decades predominating. The sexes are equally involved, and the bone lesions are most commonly located in the proximal femur, ilia, rib cage, and facial bones (138,159). Symptoms are usually related to deformity or pathologic fracture, although cranial lesions may cause progressive visual impairment or hearing loss. The polyostotic form usually presents at a younger age because of the greater involvement of the skeletal systems, and unlike the monostotic form, females outnumber males.

The lesion can be limited to a segmental defect in one extremity (monomelic form), but 25% of patients have polyostotic involvement of more than half of the skeletal system (64). About 85% of patients with this form sustain pathologic fractures, and deformities and limb-length inequality are common. Skin lesions may be present. In McCune-Albright syndrome, polyostotic fibrous dysplasia is associated with areas of cutaneous pigmentation and endocrine dysfunction (40,87,91,100,167). The skin lesions are flat and at dark brown; sometimes, extensive areas of pigmentation with irregular margins present as café-au-lait lesions. Precocious puberty is the most common endocrinopathy, but acromegaly, hyperparathyroidism, vitamin D–resistant rickets, hyperthyroidism, and Cushing's syndrome may be present. Short stature secondary to premature physeal closure is common.

Malignant degeneration is extremely rare, occurring in 0.5% to 1% (61,70,74,132,173,174). When malignant degeneration occurs, it is usually in fibrous dysplasia that has received irradiation. Do not irradiate the bone lesions of fibrous dysplasia.

Nonsurgical management of fibrous dysplasia using bisphosphonates is currently under investigation. Intravenous pamidronate has been shown to alleviate bone pain, reduce bone turnover, and improve the radiographic appearance in one series of patients with fibrous dysplasia. While these data are preliminary, bisphosphonates look promising as an effective and well-tolerated treatment (28).
PREOPERATIVE MANAGEMENT AND PLANNING

It is technically difficult to totally eradicate the disease in the absence of complete excision. Bone grafting is a temporary measure, as grafts are eventually replaced by fibrous dysplasia bone. Frequently, the goal of intervention is to maintain bone strength and integrity, or to correct deformity, not to cure the lesion. Symptomatic lesions can be treated by closed methods (splitting), curettage and bone grafting, internal fixation, and wide excision (rarely including amputation). Asymptomatic lesions do not require treatment.

Lesions in the upper extremity are usually observed or treated by closed methods. When operative intervention is necessary, internal fixation is rarely required.

Lower extremity lesions, especially involving the proximal femur, are particularly challenging and associated with significant morbidity. The patient's age at the time of symptomatic presentation seems to play a significant role in outcome. In patients older than 18 years, curettage and bone grafting appear to provide satisfactory results. In contrast, patients less than 18 years old treated by this method often sustain additional fractures, develop progressive deformity, and require additional procedures. The use of internal fixation in this group leads to a more favorable outcome (Fig. 127.19).

As with other aggressive benign entities, biopsy may occasionally be necessary to distinguish fibrous dysplasia from malignant lesions.

OPERATIVE TECHNIQUE

The proximal femur is prone to develop complex varus deformities (the shepherd's crook deformity) that are difficult to correct. In severe cases, multiple osteotomies may be necessary. Patients with McCune-Albright syndrome are a special challenge and may require multiple operative procedures to stabilize fractures, correct deformity, and graft lesions (Fig. 127.19) (116). It may be necessary to excise parts of the bone and replace them with allograft segments, but we prefer to use fibular allograft struts within the medullary cavity whenever possible.

![Figure 127.18. AP radiograph of a patient with polyostotic fibrous dysplasia who had pain in his hip. To prevent a shepherd's crook deformity, he was treated with internal fixation using a dynamic hip screw device and an allograft cortical strut to strengthen the proximal femur and femoral neck region.](image)

As with other aggressive benign entities, biopsy may occasionally be necessary to distinguish fibrous dysplasia from malignant lesions.

CLINICAL PRESENTATION AND RADIOGRAPHIC FINDINGS

Although probably not a true neoplasm, Langerhans' cell histiocytosis of bone presents with bony lesions that may be confused with benign bone tumors. It is a disorder of unknown etiology that presents with a variety of manifestations, and the tumor cells are believed to be derived from histiocytic cells resembling nonpigmented dendritic cells in the epidermis known as Langerhans' cells (162). This group of disorders is now termed Langerhans' cell histiocytosis, or granulomatosis, although traditionally it was divided into three distinct clinical entities.

The first, eosinophilic granuloma is a mild, localized, self-limited disorder of bone seldom involving more than two or three osseous sites (90,92,101,105). It occurs most commonly in the first two decades of life, but it may be seen up to the age of 50 years or beyond. Local pain or pathologic fractures through the large cystic lesion seen in the shaft of the femur. This AP radiograph of the right femur shows classic findings of polyostotic fibrous dysplasia with a shepherd's crook deformity. B: AP radiograph of the left femur shows a more severe deformity.

C: AP radiograph of the right femur after correction of the varus deformity of the hip and femoral shaft with double osteotomies and fixation with a Zickel nail. D: Lateral radiograph right femur. E: AP radiograph of the left femur after a similar procedure done at the same time as the right side. F: Lateral postoperative radiograph of the left femur. Her osteotomies healed without difficulty and she experienced significant pain relief. Her wide perineum, caused by the bilateral hip deformities, returned to normal and her gait improved substantially. At the 17-year follow-up, she has had no refractures of the femurs, has married, and has had a family. Her current problems are mainly pain in the left hip due to degenerative arthritis. (Courtesy M. W. Chapman)

LANGERHANS'S CELL HISTIOCYTOSIS (EOSINOPHILIC GRANULOMA OF BONE)

Although probably not a true neoplasm, Langerhans’ cell histiocytosis of bone presents with bony lesions that may be confused with benign bone tumors. It is a disorder of unknown etiology that presents with a variety of manifestations, and the tumor cells are believed to be derived from histiocytic cells resembling nonpigmented dendritic cells in the epidermis known as Langerhans’ cells (162). This group of disorders is now termed Langerhans’ cell histiocytosis, or granulomatosis, although traditionally it was divided into three distinct clinical entities.

The first, eosinophilic granuloma is a mild, localized, self-limited disorder of bone seldom involving more than two or three osseous sites (90,92,101,105). It occurs most commonly in the first two decades of life, but it may be seen up to the age of 50 years or beyond. Local pain or pathologic fractures through the large cystic lesion seen in the shaft of the femur. This AP radiograph of the right femur shows classic findings of polyostotic fibrous dysplasia with a shepherd's crook deformity. B: AP radiograph of the left femur shows a more severe deformity.

C: AP radiograph of the right femur after correction of the varus deformity of the hip and femoral shaft with double osteotomies and fixation with a Zickel nail. D: Lateral radiograph right femur. E: AP radiograph of the left femur after a similar procedure done at the same time as the right side. F: Lateral postoperative radiograph of the left femur. Her osteotomies healed without difficulty and she experienced significant pain relief. Her wide perineum, caused by the bilateral hip deformities, returned to normal and her gait improved substantially. At the 17-year follow-up, she has had no refractures of the femurs, has married, and has had a family. Her current problems are mainly pain in the left hip due to degenerative arthritis. (Courtesy M. W. Chapman)
The pathologic findings are similar in all involved sites and in all three variants.

**Figure 127.20.** A: AP radiograph of both femora of a 6-year-old boy with a punched-out radiolucent lesion of the left femur. There is periosteal elevation and thinning of the cortex. We were concerned about histiocytosis. Ewing's sarcoma, or infection. B: MRI shows the extent of the lesion within the medullary cavity and considerable soft-tissue swelling on this coronal image. C: Axial T1-weighted MR image shows considerable edema in the surrounding tissues. This should not be mistaken for Ewing's sarcoma, as histiocytosis commonly has significant edema surrounding the bone. After a biopsy proved that this was Langerhans' cell histiocytosis, the patient was treated with curettage. Alternatively, this lesion could have been managed with a needle biopsy and an injection of corticosteroids.

**Figure 127.21.** A: Lateral radiograph of the spine of a 10-year-old patient with typical vertebra plana involving T-10. This patient had a 20° kyphosis through the area. B: An MRI of this patient shows reduced height of the vertebral body at T-10 but maintenance of the disc space. There is no encroachment on the thoracic spinal cord. This patient was managed with a needle biopsy to confirm the diagnosis and treated in a brace with resolution of symptoms.

**PREOPERATIVE MANAGEMENT AND PLANNING**

Evaluate a patient suspected of having histiocytosis with a thorough history and physical examination. Inquire about polyuria and nocturia, eczematoid skin rashes, and otitis-like symptoms. Evaluate the bone lesion(s) with plain radiographs, and sometimes with MRI. Obtain a skeletal survey to search for other lesions. A bone scan is also useful, but on rare occasions, the bone scan may not detect lesions present on plain films. There is debate in the literature over whether bone scans or skeletal surveys are best to evaluate these patients (37,139,161,168,169). Both are useful. Obtain a first-void urine sample for specific gravity to exclude the possibility of diabetes insipidus. In a very young child, urinary catecholamines and an abdominal CT scan may be necessary to exclude the possibility of metastatic neuroblastoma or Wilms' tumor.

Biopsy lesions in the spine to exclude lymphoma, leukemia, infections, and Ewing's sarcoma. CT-directed needle biopsy is frequently possible and avoids a surgical procedure.

Vertebra plana, although frightening in appearance, seldom causes neurologic defects, and the compressed bony segment will at least partially reconstitute in height with time (73). Manage with bracing until the symptoms resolve. Opinion is divided as to whether these lesions require low-dose radiotherapy (450–900 cGy) or whether the same results might not be achieved by observation alone (63,108,142,171).

For disseminated disease, consult a pediatric oncologist. Management is frequently by chemotherapy, usually starting with vinblastine. In some patients, steroids and a variety of chemotherapy regimens, rarely necessitating bone marrow transplantation, are necessary over a protracted time to control the disease (36,85,105,124,142,152,171).

**OPERATIVE TECHNIQUE AND TREATMENT**

Treatment is nonspecific and many of the lesions of eosinophilic granuloma will disappear if left alone. Open biopsy of solitary lesions is indicated to establish the diagnosis, and this alone is frequently curative, although autogenous or allograft bone graft of the curetted cavity is advisable if a large bony defect is created. At times, internal fixation or a spica cast will be necessary to avoid fracture until the lesion heals.

Steroid injections have also been shown to be successful in the management of the bony lesions (10,142,171,175). In our experience, this can be performed at the time of CT-directed needle biopsy of long-bone lesions and is much easier for the patient.

OSTEOSARCOMA

CLINICAL FEATURES

Osteosarcoma is a high-grade primary bone neoplasm with an aggressive pattern of local growth and a marked propensity to metastasize (39,129,155). It is the second most common primary malignant bone tumor after myeloma, and accounts for 20% of all bone sarcomas. The majority of patients are in their second decade, and men and women are affected equally. Although this tumor can occur in any bone, the appendicular skeleton is most frequently involved; approximately 50% of lesions occur about the knee (138). In long bones, it tends to occur in the metaphysis. Multifocal involvement is extremely rare. Most patients present with a short history of pain and swelling in the involved limb. The pain may be intermittent at first, becoming constant later, and often accentuated at night. Because these patients are generally young and active, pain around the knee is often mistaken as a sports injury and is not recognized until the tumor has grown. Patients may present with a pathologic fracture. The majority of hematogenous metastases occur in the lungs and develop in approximately half of the patients.

Osteosarcoma has a wide range of appearances, and it is important to classify them in order to predict prognosis and design treatment (27) (Table 128.1). The classic lesion is a high-grade intramedullary osteosarcoma, which occurs in 85% of cases. Approximately 1% of cases are low-grade, well-differentiated central osteosarcomas, which have a better prognosis (9). A variant known as small-cell osteosarcoma may be difficult to distinguish histologically from Ewing's sarcoma (140). There are three types of surface osteosarcomas, including high-grade, periosteal, and parosteal lesions (10,18,108,124,139). Parosteal osteosarcoma accounts for 3% of tumors, and it has a tendency to arise on the posterior aspect of the distal femur. Its prognosis is distinctly better than the conventional lesion. Rarely, a parosteal osteosarcoma can dedifferentiate into a higher grade tumor if it is neglected or incompletely excised. The telangiectatic subtype is a high-grade, intramedullary lesion with a separate histologic appearance that must be differentiated from benign lesions such as aneurysmal bone cyst (64,120). It occurs in 3% of cases and has a prognosis similar to that of conventional osteosarcoma.
Most lesions appear to arise de novo, but secondary lesions may occur after irradiation, in Paget's disease, or as the highly sarcomatous portion of a dedifferentiated chondrosarcoma (44,45,157). Transformation should be suspected in patients with known Paget's disease who develop a sudden increase in pain. Rarely, osteosarcoma develops at the site of a pre-existing benign lesion such as fibrous dysplasia or a bone infarct. Primary osteosarcoma can also occur in the soft tissues (77).

**PATHOLOGIC FEATURES**

Osteosarcoma is defined by the presence of malignant cells producing osteoid (Fig. 128.1; see also Color Fig. 128.1). Grossly, varying amounts of soft friable tissue, firm fibrous tissue, cartilaginous tissue, and foci of ossification may be present in any given tumor. The cortex is frequently destroyed by the tumor, with extension into the surrounding soft tissues. Telangiectatic osteosarcoma is a large blood-filled tumor that may grossly appear similar to an aneurysmal bone cyst (ABC). Depending on the predominant pattern, three histologic variants of conventional osteosarcoma exist: osteoblastic, chondroblastic, and fibroblastic. However, all of these histologic subtypes of high-grade osteosarcoma have a similar prognosis. The small cell variant can be mistaken for Ewing's sarcoma under light microscopy, but current immunohistochemical and cytogentic studies can help differentiate the two lesions. Periosteal osteosarcoma has a chondroblastic histologic pattern, whereas the parosteal variant tends to be heavily ossified and have a well-differentiated fibroblastic appearance. Telangiectatic osteosarcoma has large blood-filled spaces, but a careful search reveals the characteristic malignant cells producing osteoid that differentiates it from an ABC.

**RADIOGRAPHIC FEATURES**

On plain radiographs, osteosarcoma is usually a mixed lytic and sclerotic lesion (Fig. 128.2). The tumor is aggressive with indistinct margins and evidence of cortical destruction. An extensive extraosseous mass is common. New bone formation occurs in a typical sunburst appearance of the periosteum. Some lesions may be purely lytic, particularly the telangiectatic subtype. Other lesions may be heavily ossified, such as the parosteal type, which must be differentiated from myositis ossificans. Magnetic resonance imaging (MRI) is the most useful modality for determining local soft-tissue boundaries and proximity to adjacent structures. An MRI is particularly helpful in determining the intraosseous extent of a lesion when planning surgery. The low intramedullary signal seen on T1-weighted images corresponds closely to the gross tumor extent (146). Radionuclide scans can be helpful in identifying skip lesions.

**TREATMENT**

Historically, the standard treatment for high-grade osteosarcoma was amputation. This treatment was associated with an overall 5-year survival of approximately 20%. The amputation was usually performed 8 to 10 cm proximal to the most proximal extent of the lesion, as determined by local staging studies. Despite the excellent local control achieved with amputation, pulmonary metastases developed in many patients (68,138). More effective treatment for systemic disease was needed to improve survival.

Enthusiasm for adjuvant chemotherapy was generated in the early 1970s with reports of 5-year survival increasing to between 45% and 60% (76). Other controlled trials showed no apparent survival benefits compared with surgery alone (53). However, the benefits of adjuvant chemotherapy soon became apparent, and there is now a strong consensus that it improves survival. Chemotherapy is now a component of all major osteosarcoma treatment protocols (3,52,81,98,163). The most effective agents have been methotrexate, cisplatin, doxorubicin, and ifosfamide. All standard protocols use preoperative (neoadjuvant) chemotherapy. This was historically done to allow time for the manufacture of a custom prosthesis, but preoperative chemotherapy is now used to allow more patients to undergo limb-salvage surgery and because it serves as an in vivo efficacy test of the chemotherapy itself. The extent of tumor necrosis at the time of definitive resection is used as a
measure of the tumor's response to chemotherapy, and this has been correlated with patient survival (3,116,164).

A recent multi-institutional trial for newly diagnosed, nonmetastatic osteosarcoma included high-dose methotrexate, doxorubicin, cisplatin, with or without ifosfamide and the immunostimulant MTP/PE (74). Future chemotherapy trials will incorporate the use of carboplatin. Of note, parosteal osteosarcoma is a well-differentiated low-grade tumor with a good prognosis after wide resection alone; therefore, chemotherapy is generally not used in its treatment protocol. However, periosteal plus osteosarcoma is intermediate in its biologic behavior, and in general, chemotherapy is included in the treatment protocol of this tumor.

Current research focuses on finding a way to predicting tumor response to chemotherapy before surgical resection. Then the operation can be tailored for the individual patient. Studies using various imaging modalities such as dynamic MRI and thallium scans have shown promising results (45,107). In addition, work continues on the molecular level to identify predictive biologic markers (158).

Limb Salvage

The increased success of chemotherapy combined with improved techniques of oncologic reconstruction have allowed the majority of patients with osteosarcoma to undergo limb salvage, as outlined in Chapter 126. A surgical margin can often be achieved with a limb-sparing resection that is comparable to the margin achieved with an amputation. A large multi-institutional study compared amputation with limb salvage for lesions of the distal femur and found no significant difference in local recurrence rates, as long as a wide surgical margin was achieved (121). Other investigators confirmed a low incidence of local recurrence (approximately 5%) after limb salvage (3,33). The functional results achieved with limb salvage are generally superior to those after an amputation. Most medical centers active in the management of osteosarcoma report that as many as 85% of their patients are now being treated with limb-salvage surgery (3,33), compared with fewer than 20% before 1980.

A multidisciplinary approach is necessary for treating the patient with osteosarcoma. Careful preoperative staging, including a well-planned, adequate biopsy, forms the basis of the overall treatment plan. Despite significant advances in limb salvage surgery, there remains a role for amputation. Extremely large lesions with obvious neurovascular involvement, pathologic fracture with associated contamination of multiple tissue compartments, lesions of the distal portions of the extremities, local recurrences, and lesions in the very young are situations in which the best treatment may be amputation.

The techniques used for reconstruction after resection depend on the location of the tumor and the resulting limb function expected by the patient. The alternatives after resection of all or part of a major joint include custom prosthesis, osteochondral allograft, allograft prosthetic composite, or an arthrodesis (41,134,138). Limb salvage is important for lesions of the pelvis because of the severe functional impairment after hemipelvectomy, and because the surgical margin that is achieved often may be the same as that achieved by amputation. The use of current techniques depends on the location and extent of pelvic resection. With complete ilipectral joint resection, fusion of the remaining ilium to the sacrum can be achieved by hinging the pelvis on the symphysis pubis. After periacetabular resection, the proximal femur can be fused to the ilium or pubis. This construct is enhanced by the use of vascularized fibular grafts or intercalary allograft segments. The resultant large discrepancy in limb length can be corrected by bone transport of the femur in selected cases. A sdiale prosthesis is an option if enough ilium remains to obtain a stable attachment (1). Some patients function quite well after periacetabular resection without reconstruction by developing a painless pseudarthrosis. Allograft reconstruction of the pelvis combined with prosthetic hip replacement has been successful, but this complicated technique is often fraught with postoperative complications such as allograft fracture, prosthetic loosening, or infection.

Prosthetic replacement has been particularly effective in restoring function of the hip joint after resection of a proximal femoral osteosarcoma (135) (Fig. 128.2). A custom prosthesis or an allograft prosthetic composite are good choices, with an allograft prosthetic composite used more often in younger patients to restore bone stock for future needs.

There are multiple options for reconstruction after resection of an osteosarcoma around the knee joint. Extra-articular resection and arthrodesis provide a durable limb and are an option in a very young patient (129). Techniques can be used to lengthen the limb after completion of chemotherapy to avoid a large limb-length discrepancy (112). Segmental arthrodesis can be accomplished by various methods. An effective method is use of hemicylindrical femoral turn-down or tibial turn-up grafts combined with ipsilateral fibular grafts and a long intramedullary rod with small antirrotational plates at the host–graft junction for stabilization. At present, more surgeons use an intercalary allograft segment to span large defects and facilitate the arthrodesis. Use of an osteocarticular allograft has the advantage of being a biologic solution in a young patient; however, there is a high likelihood of complications in the first several years after surgery (89) (Fig. 128.3). At present, our preferred limb-salvage technique is a modular total knee replacement using a rotating hinge design. This provides immediate functional restoration and long-term durability, which has been improved with modern implants (19,21,33,86). Difficulty arises when the proximal ilia is replaced with a metal prosthesis because there is still no ideal method for reattaching the extensor mechanism to the prosthesis. (See Chapter 126 for some alternatives.) An allograft prosthetic composite is an effective procedure to provide restoration of bone stock and allow improved extensor function (62). The extensor mechanism is reattached to the allograft tendon and a rotational gastrocnemius flap is used to cover the allograft bone and tendon.

Figure 128.3. A, B: AP and lateral views of the right distal femur in a 35-year-old woman demonstrating a heavily mineralized lesion consistent with a parosteal osteosarcoma emanating from the posterior cortex. This particular subtype of osteosarcoma is less aggressive than its conventional counterpart. C: Sagittal section through the gross specimen. The majority of the medullary cavity is free of tumor. D, E: AP and lateral radiographs of the distal femur after wide resection and reconstruction using an osteocarticular allograft.

Osteosarcoma of the upper extremity commonly involves the shoulder. Resection of the proximal humerus often requires sacrifice of the rotator cuff muscles, overlying deltoid, and axillary nerve (85,90). Reconstructive options include prosthetic replacements that use a modular design with a porous coating for potential bone ingrowth. Arthrodesis using dual fibular grafts, vascularized fibular grafts, or allografts has also been successful (89) (Fig. 128.4). If the axillary nerve and a portion of the deltoid arises from the proximal humerus, a Tikoff-Lindberg procedure is required, with placement of a metal spacer attached to the remaining chest wall to provide shoulder stability (see Chapter 126).

Figure 128.4. A: AP view of the proximal end of the right humerus in a 15-year-old girl with an extensive osteosarcoma. She has no evidence of metastatic disease. B: Postresection arthrodesis in which an intercalary allograft was combined with a vascularized fibular graft. The soft-tissue extent of the tumor necessitated sacrifice of
In very young patients, when resection or reconstruction of a limb involves the physeal plate, the limb-length discrepancy at adulthood may be substantial. Options that allow limb salvage for young patients include the use of an expandable prosthesis or a rotationplasty (61,152,162). The Ilizarov technique for limb lengthening and bone transport may have a role in the management of skeletal defects in young patients (112). Innovative methods of physeal distraction to improve the marginal resection and preserve the articular surface have been described.

RESULTS OF TREATMENT

With advances in chemotherapy and surgical techniques, the outlook for patients with osteosarcoma continues to improve. The increase in limb-sparing surgery has not adversely affected survival. The multi-institutional study that looked at lesions in the distal part of the femur found no difference in survival among patients treated by limb salvage and those treated by amputation (141). Sim and colleagues (138) also found no adverse effects of limb-sparing surgery when compared with amputation. Current 5-year survival rates after a multidisciplinary approach are between 65% and 70%. The survival rate is as high as 80% in patients with extremity lesions who have an apparent good response (greater than 90% necrosis) to preoperative chemotherapy (3). In patients using multiple chemotherapeutic agents, one recent study showed a 10-year survival of 88% (99). The Mayo Clinic pilot study using ifosfamide-based chemotherapy showed an actuarial survival rate of greater than 90% at 2.5 years (98). For patients with metastases at diagnosis, only 40% remained free of progression of their disease at 2 years. The outlook in patients with systemic disease remains poor, although there are reports of long-term survival for patients treated with an aggressive surgical approach, including multiple thoracotomies and systemic chemotherapy (21) (Fig. 128.5). Patients who develop local recurrence of their osteosarcoma have a poor prognosis (115,141,148).

CHONDROSARCOMA

CLINICAL FEATURES

Chondrosarcoma of bone is a malignant tumor of proliferating cartilage tissue (39,63,129,155) (Table 128.2). It accounts for approximately 10% of malignant bone tumors and tends to occur in older adults; the peak incidence is in the fifth to sixth decades of life. More than 75% of these lesions are located in the trunk or proximal portions of the femur or humerus. The inner wall of the acetabulum is a particularly common site. When it is found in the extremities, chondrosarcoma occurs centrally within the intramedullary portion of the bone. The lesions tend to grow slowly, and pain may be experienced for months or years before a mass or swelling is detected. Metastasis is generally to the lung but is rare in low-grade lesions and often occurs late in the course of the disease. However, the tumor has a tendency to recur locally (89–121).

Mesenchymal chondrosarcoma is an extremely rare, highly malignant cartilage lesion with a bimorphic histologic appearance (66,102). It tends to occur in patients who are in their second or third decade. Two thirds of the lesions occur within the bone, and the remainder arise in the soft tissues. Clear cell chondrosarcoma is the least common of the chondrosarcoma subtypes. It is a low-grade malignant tumor with a predilection for the ends of long bones, particularly the proximal femur and humerus (11). Patients are usually in the third or fourth decades of life, and symptoms of vague pain can be present for years before discovery of the lesion. Dedifferentiated chondrosarcoma is a highly malignant variant that accounts for approximately 10% of chondrosarcomas. It is a high-grade noncartilaginous sarcoma that arises within a pre-existing low-grade chondrosarcoma (45,83).

Chondrosarcoma may arise de novo as a primary lesion, or it may occur secondarily at the site of a previous benign lesion such as an osteochondroma or enchondroma (47,103). More than 75% are primary tumors. Patients with multiple benign cartilage tumors, such as in Ollier’s disease, Maffucci’s syndrome, or multiple hereditary osteochondromas, are more likely to develop a secondary chondrosarcoma than are patients with solitary lesions.

PATHOLOGIC FEATURES

Chondrosarcoma tends to be lobular with a matrix of varying consistencies (Fig. 128.6; see also Color Fig. 128.6). The center of the lobules often undergoes myxoid degeneration. Cortical destruction with soft-tissue extension is common, and calcific densities are frequently found within the chondroid matrix. This tumor has been divided into three histologic grades. Approximately 90% are well-differentiated (grade 1 or 2) tumors. In general, the grade of the tumor correlates with its cellularity (87,88). It is important to differentiate high-grade chondrosarcoma from chondroblastic osteosarcoma. Chondroblastic osteosarcoma has marked cytologic atypia and osteoid production. It is also often difficult to differentiate a low-grade chondrosarcoma from an enchondroma. Therefore, it is extremely important to correlate the clinical, radiographic, and histologic presentations before rendering a final diagnosis. Usually, a chondrosarcoma has more pleomorphic cells and may have myxoid changes within the chondroid matrix. Binucleation of the cells is not a distinguishing feature because it can be seen in both lesions. Chondrosarcoma of the small bones of the hand and foot is rare, and clinical and radiographic correlation is necessary to differentiate it from a benign cartilage lesion. Enchondromas in these sites are very common, but they have a much more aggressive histologic appearance than their long-bone counterparts. This makes the diagnosis difficult based on histology alone.
Grade I chondrosarcoma. The lesion is quite cellular, the nuclei are enlarged and irregular, and double nucleated cells are present.

An important subtype of chondrosarcoma is the dedifferentiated lesion. Grossly, there is an abrupt transition from the centrally located hyaline component to the spindle cell portion. Histologically, it is characterized by sheetlike regions of highly anaplastic spindle cell sarcoma immediately adjacent to lobules of well-differentiated chondrosarcoma. The spindle cell component may show features of osteosarcoma, fibrosarcoma, or malignant fibrous histiocytoma. Another subtype, clear cell chondrosarcoma, has a cartilagenous matrix and is variably lobulated under low power. There are areas of mononuclear and multinucleated giant cells. The tumor cells have abundant clear cytoplasm and distinct boundaries. Mesenchymal chondrosarcoma is grossly well defined, with calcific foci scattered throughout the tumor. The low-power pattern is bimorphic, with islands of benign-appearing hyaline cartilage among highly cellular areas of uniform, small, round, or spindled cells. There are numerous branching vessels with a pattern reminiscent of hemangiopericytoma.

**RADIOGRAPHIC FEATURES**

Chondrosarcoma appears as a predominantly lytic lesion that arises in the medullary cavity but usually involves the cortex as well. Eventually it extends through the cortex and forms a large soft-tissue mass. Matrix calcification is present in the majority of tumors and appears as rings of mineral. Endosteal scalloping and cortical expansion are characteristic of a chondrosarcoma, as opposed to a benign enchondroma. In long bones, the tumor is usually metaphyseal or metadiaphyseal in location. Periosteal chondrosarcoma is a rare variant that arises de novo on the surface of the bone. A tumor arising in the pelvis is less distinct on plain films but is often associated with a characteristic large soft-tissue mass and mottled mineralization. Computed tomography (CT) and MRI can help define soft-tissue margins and cortical destruction in pelvic tumors. Both are useful in detection of recurrent lesions. If the cartilage cap on an osteochondroma exceeds 2 cm on MRI or CT scan in a patient with clinical symptoms, consider secondary chondrosarcoma.
chondrosarcoma has the appearance of a conventional chondrosarcoma when it arises in bone. Matrix calcification is present when it occurs in the soft tissues.

TREATMENT

Surgical resection remains the mainstay of therapy for chondrosarcoma (12,121,133). Two important principles apply in surgical management. First, a well-planned and adequate biopsy that is representative of the entire tumor is necessary. Second, a wide margin must be achieved at initial resection to ensure the best chance of cure for this tumor, which is notorious for local recurrence. Accurate preoperative staging with determination of the histopathologic grade and regional tumor extent dictates the aggressiveness needed at operation. For lesions of higher grade with extensive soft-tissue and neurovascular involvement, amputation may be required to ensure local control. Even lower grade lesions that have recurred in the pelvis often involve the neurovascular bundle and necessitate external hemipelvectomy. When a limb-sparing procedure is feasible, the reconstructive techniques described for osteosarcoma apply equally well for chondrosarcoma (1,19,23,35,41,62,85,90,128,134) (Fig. 128.7, Fig. 128.8, and Fig. 128.9). Internal hemipelvectomy and iliofemoral fusion for pelvic lesions have yielded satisfactory results. For lesions involving the proximal femur, a custom prothetic replacement or an allograft prosthetic composite is an effective reconstructive option after proximal femoral resection. In general, chondrosarcoma is resistant to chemotherapy and radiation.

Of the chondrosarcoma variants, clear cell chondrosarcoma is curable after wide resection. Mesenchymal chondrosarcoma also necessitates an aggressive surgical approach to achieve a wide resection margin. One report found radiation and chemotherapy to be beneficial in a subset of these tumors (68). Dedifferentiated chondrosarcoma has a dismal prognosis, despite radical surgical resection and adjuvant therapy.

RESULTS OF TREATMENT

The overall survival rate for a patient with conventional chondrosarcoma is highly dependent on the histologic grade (12). A survival rate of 94% for grade 1, 61% for grade 2, and 44% for grade 3 at 5 years was reported in one study (60). Because local recurrence affects survival adversely and late recurrences are common, 5-year survival rates are unreliable indicators of long-term results. A 10-year survival rate of 77% for grade 1, 59% for grade 2, and 36% for grade 3 lesions was documented in another study (121). Local recurrence occurs in 20% and pulmonary metastases in 15% (12).

A wide resection of clear cell chondrosarcoma is generally curable. Patients treated with intralesional curettage have an 80% risk of local recurrence, with metastases to the lung and other skeletal sites (11). Patients with mesenchymal chondrosarcoma have a survival rate of 50% at 5 years and 28% at 10 years (68,102). Results of treatment of highly malignant, dedifferentiated chondrosarcoma are poor despite radical surgery. The 5-year survival rate is approximately 10% (45,95).

EWING’S SARCOMA

CLINICAL FEATURES

Ewing’s sarcoma of bone is a highly anaplastic, small, round cell tumor of neuroectodermal origin (39,54,129,155,156) (Table 128.3). Ewing’s sarcoma is the second most common primary malignant bone tumor in children and the fourth most common malignant bone tumor in all ages. It occurs slightly more often in male patients and almost never in the black population. The tumor occurs typically in the first and second decades of life, more than 90% of patients are younger than 30 years of age. It can arise in any part of the body, but more than 60% of the lesions occur in the pelvic girdle and lower extremities. When it occurs in the long bones, the diaphysis is usually involved. Ewing’s sarcoma can also occur in the soft tissues (126).

PATHOLOGIC FEATURES

The tumor is characteristically gray or white and has a semliuid consistency that suggests purulence (Fig. 128.10; see also Color Fig. 128.10). Microscopically, it is a cellular sheetlike proliferation of small round cells without matrix production. However, fibrous strands may be identified traversing the lesion. The cells have indistinct cytoplasmic borders with round or oval nuclei. It may be difficult to differentiate Ewing’s sarcoma from other round cell tumors such as lymphoma, embryonal rhabdomyosarcoma, metastatic neuroblastoma, and small cell osteosarcoma by light microscopy alone. In recent years, great strides have been made using immunohistochemical and molecular genetic methods to differentiate Ewing’s sarcoma from other small round cell tumors (Table 128.4). Cytogenetic studies have revealed a reciprocal translocation (11;22) (q24;q12) found in both Ewing’s sarcoma and primitive neuroectodermal tumor (PNET). Reverse transcriptase polymerase chain reaction (RT-PCR) assays can be used to look for this translocation even if traditional cytogenetic testing is unsuccessful (28,131). Other translocations have also been identified. In addition, these tumors have a cell surface glycoprotein called p30/32 MIC2, which is a product of the MIC2 gene located on the short arms of the X and Y chromosomes. This glycoprotein can be recognized by commercially available monoclonal antibodies.

Table 128.4. Ewing’s Sarcoma—Ancillary Studies
Fibrosarcoma of bone is a rare malignancy characterized by the proliferation of spindle cells without any discernible matrix production. Clinically, fibrosarcomas may behave like benign tumors, except for the presence of pain. Chemotherapy is usually not helpful, although it can be used for patients with metastatic disease. Surgical excision with a wide margin is the primary treatment of choice, and local control rates are high. The prognosis is generally better for soft-tissue fibrosarcoma than for bone fibrosarcoma. The role of radiation therapy is limited to the treatment of local recurrences. Overall, the 5-year survival rate for fibrosarcoma is approximately 60%.}

**Radiographic Features**

Ewing's sarcoma usually originates in the intramedullary cavity and commonly involves an extensive portion of the diaphysis of a long bone. Lytic destruction in a mollified or moth-eaten pattern is the most common radiographic appearance. The margins are indistinct and the actual bone involvement seen on plain films may be subtle. Cortical destruction with periosteal elevation and multiple layers of subperiosteal new bone gives the classic "onion skin" appearance; however, this is not pathognomonic for Ewing's sarcoma. Radiating spicules of new bone in a sunburst pattern can also occur, making radiographic differentiation from osteosarcoma difficult. In rare lesions with little or no intramedullary involvement (e.g., subperiosteal Ewing's sarcoma), saucer-shaped destruction of the exterior cortex is a fairly characteristic feature. As in other malignant tumors, MRI is most helpful in defining the soft-tissue extension that is common in Ewing's sarcoma.

**Treatment**

The mainstay of treatment for Ewing's sarcoma is multiagent chemotherapy. Over the past 20 years, multi-institutional chemotherapy studies have greatly enhanced our ability to increase the long-term survival rates in patients with this disease. In 1981, the first Intergroup Ewing's Sarcoma Study Group (IESS-I) demonstrated that adding doxorubicin (Adriamycin) to the standard regimen of vincristine, cyclophosphamide, and actinomycin-D increased survival. IESS-II showed that dose intensification of the four-drug regimen gave a significant improvement in disease-free and overall survival. Seventy-three percent of patients with nonmetastatic, nonpelvic disease were relapse free at a median follow-up of 5.6 years. IESS-III compared the intensified four-drug regimen with a similar protocol with the addition of ifosfamide and etoposide. There was an overall improvement in disease-free survival with the six-drug regimen that was most striking in the young age group and in patients with pelvic tumors. Current national cooperative studies are comparing the standard six-drug regimen with use of these agents over a shorter time course with intensification of ifosfamide and cyclophosphamide.

As a small round cell tumor, Ewing's sarcoma is considered to be radioresistant. In the past, radiotherapy protocols consisting of 4000 to 6000 cGy were delivered to the affected bone to provide the primary means of local control along with chemotherapy. However, radiation inconsistently controlled the primary tumor, and local recurrence rates were 15% to 20% after treatment. Microscopically viable tissue was found in 65% of these patients in autopsy studies. The late morbidity associated with irradiation includes limb-length inequality, pathologic fracture, fibrosis, and ankylosis. The increased possibility of radiation-induced sarcoma led to a renewed interest in the role of surgical treatment for local control of Ewing's sarcoma. As with osteosarcoma, a favorable response to neoadjuvant chemotherapy can lead to an increased interest in the role of surgical treatment for local control of Ewing's sarcoma. As with osteosarcoma, a favorable response to neoadjuvant chemotherapy can lead to a renewed interest in the role of surgical treatment for local control of Ewing's sarcoma.

**Results of Treatment**

Before effective chemotherapy was available, Ewing's sarcoma was considered one of the most lethal sarcomas, with a 5-year survival rate of less than 20%. With a modern, multidisciplinary approach to treatment, the overall 5-year survival rate has improved to greater than 70%. As with osteosarcoma, a favorable response to neoadjuvant chemotherapy is a good prognostic sign. Survival rates as high as 80% to 90% have been reported for patients with extremity lesions who have more than 90% necrosis after neoadjuvant treatment. In addition, patients with distal tumors have an improved prognosis compared with those with central lesions in the pelvis or sacrum. Poor prognostic variables include large tumor size, pelvic location, metastatic disease at initial presentation, and poor response to neoadjuvant chemotherapy. A review of 140 patients at the Mayo Clinic, 25% presented with metastatic disease. The 2-year survival rate of this subset was 39% compared with those with nonmetastatic disease, who had a 2-year survival rate of 69%.

**Fibrosarcoma**

**Clinical Features**

Fibrosarcoma of bone is a rare malignancy characterized by the proliferation of spindle cells without any discernible matrix production. This tumor...
accounts for less than 4% of primary osseous malignancies and occurs in patients from the second through sixth decades of life. Patients with fibrosarcoma have an age distribution different from those with fibroblastic osteosarcoma, although the tumors may be similar histologically. Men and women are affected equally. The skeletal distribution is similar to that of osteosarcoma, with more than 50% occurring in long bones, usually the femur or tibia. Most of these lesions arise de novo, but 25% can be considered secondary, arising at sites of pre-existing disease or after irradiation. Symptoms of fibrosarcoma include pain and swelling, which may exist for a long time before diagnosis. Fifteen percent of patients present with a pathologic fracture. Fibrosarcoma metastasizes to the lungs in a high proportion of cases.

PATHOLOGIC FEATURES

Fibrosarcoma varies in gross appearance (Fig. 128.12; see also Color Fig. 128.12). Some well-differentiated lesions may be firm, dense, and seemingly well circumscribed. Poorly differentiated lesions tend to be soft and friable with regions of myxoid degeneration. Areas of hemorrhage and necrosis are frequently evident. Cortical destruction is common, and soft-tissue involvement may be extensive. Fibrosarcoma has the same histologic features as its soft-tissue counterpart; however, it infiltrates through and destroys the bone (8). It is characterized by spindle cells arranged in a herringbone pattern. The cells form interlacing bundles of collagen fibers. They show varying degrees of cytologic atypia and stroma production. Some lesions are so well-differentiated that they can be confused with benign fibrous lesions such as desmoplastic fibroma (155). Other tumors are highly anaplastic, with little or no recognizable collagenous stroma. Approximately 68% of the lesions are grade 3 or 4.

Figure 128.13. A, B: AP and lateral radiographs of the right distal femur in a 25-year-old woman with fibrosarcoma. There has been cortical destruction along the medial femoral cortex. C, D: Extra-articular resection, followed by allograft arthrodesis, which is solidly healed three years later.

TREATMENT

Adequate treatment requires wide surgical resection. If it is apparent that a wide margin cannot be obtained to achieve local control, an amputation is required. The principles and techniques of limb-sparing surgery to preserve function yet achieve local tumor control have been previously discussed (19, 23, 134). The reconstructive choices are similar to those for osteosarcoma and chondrosarcoma (Fig. 128.13).

Radiation therapy is usually ineffective, although it may have a palliative role in lesions deemed unresectable. Neoadjuvant multidrug chemotherapy programs similar to those used for osteosarcoma are being recommended for treatment of systemic disease, although long-term results are not available (8, 65).

RESULTS OF TREATMENT

Fibrosarcoma of bone portends a poorer prognosis than those of the soft tissues (122, 150, 151). It behaves similar to malignant fibrous histiocytoma of bone. In recent studies, the 5-year survival rate for fibrosarcoma is approximately 45% with or without adjuvant treatment (113). This reflects the improved preoperative staging and sophisticated imaging modalities compared with those of prior eras (85). As with other spindle cell sarcomas, the prognosis relates to the histology with low-grade, well-differentiated lesions having a distinctly better prognosis than high-grade tumors (65, 122). Other factors associated with a poorer prognosis for survival include age greater than 40 years and location of the tumor in the axial skeleton. Metastases, primarily to the lung, are reported in up to 75% of patients with this rare tumor. Therefore, development of effective adjuvant chemotherapy protocols is a priority. Treatment of the metastatic lesions with aggressive thoracotomy has been reported...
MALIGNANT FIBROUS HISTIOCYTOMA

CLINICAL FEATURES

Malignant fibrous histiocytoma of bone is a highly malignant neoplasm. It has previously been difficult to differentiate from fibrosarcoma and fibroblastic osteosarcoma, but it is now recognized as a distinct clinicopathologic entity. The histogenesis of this tumor is debated, but many believe that it is derived from primitive mesenchymal cells. It is similar to its soft-tissue counterpart but much less common, accounting for approximately 5% of malignant bone tumors. Arising in patients of any age, it reaches its peak incidence in the fourth and fifth decades, and it occurs slightly more frequently in male patients. Malignant fibrous histiocytoma occurs as a metaphyseal lesion in the appendicular skeleton, particularly around the knee, but it can also be found in the pelvic and axial skeleton. Patients present with pain with or without swelling. Occasionally, a pathologic fracture is noted at initial presentation.

Approximately 25% of malignant fibrous histiocytomas arise as secondary tumors in pre-existing conditions such as bone infarcts or Paget's disease. They also occur as the predominant histologic type in postirradiation sarcomas and the sarcomatous portion of dedifferentiated chondrosarcomas.

PATHOLOGIC FEATURES

The tumors vary in consistency from firm to soft, depending on the amount of fibrous tissue they contain. They are typically gray to yellow, with areas of necrosis and hemorrhage. Cortical destruction and soft-tissue extension are prominent features. Malignant fibrous histiocytoma has a pleomorphic pattern at low magnification. The tumor contains both malignant spindle cells and malignant histiocytic cells. The spindle cell regions have a matted or storiform pattern reminiscent of primary soft-tissue lesions. Considerable cytologic variation is identifiable at high magnification. Histiocytic appearance is characterized by indentation of nuclei and large, well-defined cytoplasm. Other cells show a spindle cell arrangement with ovoid to ellipsoid nuclei. The vast majority of lesions are high grade. Osteoid or chondroid matrix production by the tumor cells precludes a diagnosis of malignant fibrous histiocytoma. Differentiation from fibrosarcoma may be difficult. The particular histologic features of this tumor have no prognostic significance.

RADIOGRAPHIC FEATURES

Malignant fibrous histiocytoma is radiographically characterized by geographic lysis, but occasionally, there is a permeative picture. Cortical destruction and indistinct margins suggest an aggressive malignancy. There is a wide zone of transition from normal to abnormal bone. Little reactive periostea or sclerotic bone is seen. Radionuclide scans are helpful in detecting other lesions. CT and MRI scans confirm the cortical destruction and aid in determining soft-tissue margins and the relation of the tumor to adjacent neurovascular structures.

TREATMENT

The treatment of malignant fibrous histiocytoma is similar to that of other high-grade bone tumors. Surgery is the mainstay of treatment, and the goals of adequate surgical control with maximal preservation of limb function determine the feasibility of limb-sparing surgery. Often, a pathologic fracture or extremely large soft-tissue mass that comprises neurovascular function will necessitate amputation. Lesions that cannot be adequately excised or present in problematic locations may be treated with adjuvant or primary radiotherapy. Occasional long-term survivors have been reported after treatment with radiation only.

Because this is such a rare tumor, few reports documenting the effect of chemotherapy have been published. Picci et al. report an increased disease-free survival rate of 67% at median 7 years using a neoadjuvant chemotherapy protocol similar to that used for osteosarcoma. However, effective tumor necrosis was seen in only 25% of patients. The overall survival rate for patients treated surgically in the Mayo study is approximately 52% at 5 years and 41% at 10 years. Inadequate surgical margins, metastatic disease at presentation, age greater than 40 years, and axial tumor location have been correlated with a poorer prognosis. Local recurrence is increased after inadequate surgical margins. There is debate on whether the prognosis is worse in patients with a secondary malignant fibrous histiocytoma. Metastasis occurs hematogenously, usually to the lungs but also to other osseous sites. Patients occasionally can be cured with aggressive resection of pulmonary lesions.

MYELOMA

CLINICAL FEATURES

Myeloma is a neoplastic disease of plasma cells that involves the bone marrow. It has a wide clinical spectrum of disease, accounting for the variety in its presentation. It is most commonly manifested by widespread skeletal involvement with marked overproduction of monoclonal immunoglobulins. Myeloma is the most common primary malignancy of bone, accounting for approximately half of all bone tumors. Most patients are between 50 and 70 years old. The most common tumor locations are in bones that contain active hematopoietic elements; more than 85% of the lesions involve the axial skeleton and proximal portions of the
Femur and humerus.

Table 128.6. Plasma Cell Proliferative Disorders

Pain is a prominent feature of myeloma, particularly if a pathologic fracture occurs. Systemic symptoms of weakness and fatigue, along with abnormal laboratory findings, are helpful in establishing a diagnosis. Systemic amyloidosis occurs in 15% of patients with multiple myeloma. Patients have a characteristic immunoglobulin profile that can be demonstrated with immunoelectrophoresis. This particular finding is one part of a set of specific criteria necessary to diagnose myeloma accurately. Diagnosis of multiple myeloma is based on one major and one minor, or three minor, diagnostic criteria, as outlined in Table 128.7. It is important to differentiate this tumor from metastatic disease, which occurs in a similar age group and causes similar clinical symptoms. The classic staging system of Durie and Salmon (31) identifies patients at risk for shortened survival.

Table 128.7. Multiple Myeloma—Diagnostic Criteria

Presentation with a solitary osseous lesion (plasmacytoma), which is defined as the concurrent finding of a positive biopsy of an isolated lesion, a negative bone marrow aspirate, and a negative skeletal survey, occurs in approximately 25% of patients (43). Subsequent dissemination of the disease occurs in more than 50% of these patients by 10 years. More than half of the solitary osseous lesions are located in the vertebral column (78). Solitary extramedullary plasmacytomas, often located in the upper airway passages, can occur alone or in patients in whom multiple myeloma later develops.

Osteosclerotic myeloma occurs in 1% of cases and can be associated with POEMS syndrome (Table 128.8). These patients have an increased incidence of peripheral neuropathy (73). In general, osteosclerotic myeloma occurs in younger patients and has a more indolent course.

Table 128.8. Multiple Myeloma—Poems Syndrome

**PATHOLOGIC FEATURES**

Myeloma is typically soft, gray to red, and friable (Fig. 128.16; see also Color Fig. 128.16). The gross boundaries are indistinct, and often the medullary and extramedullary involvement is greater than anticipated. Microscopically, the tumor consists of sheets of closely packed plasma cells. The cells are homogenous, with eccentric nuclei having a clumped chromatin pattern. There is abundant granular cytoplasm, and multinucleated cells are occasionally seen. A variable amount of pink, amorphous amyloid is present in 10% to 15% of myelomas (144).

Figure 128.16. (See Color Fig. 128.16.) Sheets of plasma cells typical of myeloma. There is abundant pink cytoplasm, and the nuclei are structured eccentrically.
RADIOGRAPHIC FEATURES

The classic plain film appearance is of purely lytic "punched-out" areas of bone destruction (Fig. 128.17). The lesions are small and uniform. Typically, there is no reactive zone of sclerosis. A ballooning expansion of bone may occur, particularly in rib lesions. Osteosclerotic lesions are either osteoblastic or mixed in appearance (123). In 15% to 25% of patients, no discrete lytic occurs, and diffuse osteopenia and osteoporosis are the only skeletal manifestations. MRI can help define the lesion when there is nothing definite on plain films. Technetium 99m bone scans are less reliable in identifying myeloma lesions because of a lack of osseous response to the tumor. A skeletal survey with plain tomography or CT is more helpful in finding additional lesions or defining the extent of osseous destruction. Sixty percent of patients develop pathologic fractures, with the majority being vertebral compression fractures.

TREATMENT

Standard treatment for multiple myeloma aims at control of the lesion; complete cure is rare. The primary systemic modality for patients with multiple myeloma is chemotherapy. Most protocols include the use of melphalan (L-phenylalanine mustard) and prednisone (52). Combination chemotherapy has not been definitively shown to prolong overall survival compared with the above-mentioned agents in randomized trials (109,115). A positive response to treatment can be monitored objectively by observing a decrease in M-type proteins, the rate of hematologic recovery, and occasionally, resolution of the skeletal disease. No single test can be reliably used to follow multiple myeloma, but serum protein electrophoresis or test for quantitative immunoglobulins is probably the most reasonable. Recent work using interventions such as interferon and peripheral stem cell transplantation is promising (61). In addition, biologic substances such as interleukin-6 are being targeted in cytokine growth factor–directed treatment (53). Despite this and other exciting new molecular work, there has been almost no improvement in the overall survival of the patient in the last 20 years.

Radiation is very effective for localized lesions that are causing disabling pain or limitation of activity. Radiation tends to slow the growth of the tumor, which allows microfractures to heal. Occasionally, the lesion reossifies with a return of structural integrity. This, along with occasional bracing, is the standard treatment for patients with vertebral involvement. An aggressive approach to therapy is warranted for patients with solitary myeloma. A radiation dose of 4500 cGy to the solitary lesion has been shown to prevent local recurrence (43). Localized extramedullary disease of the upper respiratory tract can be cured with radiation (59).

Surgical intervention in multiple myeloma is indicated for patients with vertebral involvement who have compressive paraplegia and for patients with impending or actual pathologic fractures. Decompressive laminectomy is indicated if radiation does not cause resolution of symptoms, and moderate to excellent return of function can be expected. Spinal stabilization is occasionally warranted, and recent advances in the techniques of anterior and posterior instrumentation have improved the effectiveness in restoring stability (79).

Pathologic fractures require aggressive surgical management to relieve pain and maintain ambulatory status (Fig. 128.17). The indications for prophylactic internal fixation of an impending pathologic fracture are the same as those used in metastatic disease (67,79,97,136,137). The principles of open reduction and internal fixation, often using supplemental methylmethacrylate, can achieve skeletal stability in most of these fractures (167). For those involving the femoral neck, resection and prosthetic replacement are effective (114,435). For subtrochanteric lesions, our preferred technique is the use of a reconstruction nail with methylmethacrylate augmentation. If there is extensive involvement of the proximal femur, a standard sliding hip screw and side plate has been shown to fail with progression of the disease; therefore, more extensive reconstruction techniques, including proximal femoral replacement, may be indicated. A more aggressive surgical approach is warranted in a patient with a solitary plasmacytoma because survival may be prolonged.

RESULTS OF TREATMENT

The overall prognosis for patients with multiple myeloma is poor because patients tend to die within 3 years of diagnosis. The 5-year survival rate is 18% for multiple myeloma, with a median survival time of 20 months and a 1-year survival rate of 66% (78). Chemotherapy improves the median survival time to 3 years in the 50% to 60% who respond to treatment. Poor prognostic variables include the presence of M-proteins, pancytopenia, hypercalcemia, diffuse skeletal lesions, and renal failure. New biologic assays are emerging that identify patients who are likely to have long-term survival. Young patients with a low b2M level and a low plasma cell labeling index have a better prognosis, according to recent studies (51).

The overall survival rate of patients with solitary plasmacytoma is 74% at 5 years and 45% at 10 years. Fifty percent of patients progress to multiple myeloma (6,43).

MALIGNANT LYMPHOMA OF BONE

CLINICAL FEATURES

Malignant lymphoma of bone is a neoplasm of the reticuloendothelial system. It accounts for approximately 3% of primary osseous malignancies; an equal number of cases represent secondary osseous involvement. Non-Hodgkin's lymphoma is three times more likely to have bone involvement compared with Hodgkin's disease. There are well-described and useful classification and staging systems for both types of lymphoma (17). Any age group can be affected, but it is rare in the very young and peaks in the fifth to seventh decades of life. In primary lymphoma of bone, the lesions tend to be diaphyseal or metaphyseal, occurring in the proximal femur, proximal humerus, and distal femur. In disseminated disease, the bony involvement is commonly in the axial skeleton, including the pelvis and spinal column (55,155).

Pain, often present for many months or years, is a constant feature. Neurologic symptoms are common with spinal lesions, as are pathologic fractures. Systemic disease is either via hematogenous spread or direct, contiguous extension from the nearby soft tissues or lymph nodes.

PATHOLOGIC FEATURES

Gross inspection reveals a gray-white tumor with an infiltrative growth pattern and frequent soft-tissue extension (Fig. 128.18). The tumor is generally soft if it has completely destroyed the bone but is firm if residual osseous trabeculae exist. Areas of necrosis may be present. Extraosseous masses are usually soft and friable. Microscopically, the tumor consists of an admixture of large and small cells amid a fine reticulin meshwork. It is composed of a proliferation of histiocytes and lymphoid cells at various stages of differentiation. Most common is the diffuse large-cell, B-cell phenotype. Varying degrees of fibrosis may be present. Histologically, primary malignant lymphoma of bone is indistinguishable from a lymphoma originating elsewhere. Immunohistochemical markers can help identify and subclassify these tumors.
Figure 128.18. (See Color Fig. 128.18.) Malignant lymphoma demonstrating proliferation of large cells with irregular nuclei. There is no matrix.

RADIOGRAPHIC FEATURES

Primary lymphoma of bone tends to be located in the metadiaphyseal region, although 25% to 100% of the bone may be involved in a mottled or patchy fashion on plain radiographs. The margins are indistinct, with marked cortical destruction and soft-tissue extension. In some lesions, there is cortical thickening. There is usually no matrix mineralization. At times, plain radiographic changes may be subtle, but MRI scans show diffuse marrow signal change. Differentiation from Ewing's sarcoma, metastatic carcinoma, osteomyelitis, and Paget's disease may be difficult.

TREATMENT

It is extremely important to obtain accurate clinical staging of the patient with lymphoma. In the past, inadequate staging has confused the analysis of clinical outcome. Routine blood counts and chemistries, chest radiograph, chest/abdomen/pelvis CT scan, and bilateral bone marrow biopsies are required. The primary treatment of lymphoma of bone is radiation. The entire bone is treated with 4000 cGy, with a boost to the affected region of 4500 to 5000 cGy. Local control up to 85% has been reported. Chemotherapy is generally advocated for systemic disease, and different regimens are used for Hodgkin's and non-Hodgkin's lymphoma. Surgery is reserved for impending or actual pathologic fractures that cannot be managed reasonably by other means. Surgery is also indicated for isolated, uncontrolled lesions of an extremity that have failed to respond to radiation treatment.

Figure 128.19. A, B: AP and lateral radiographs of the left distal femur in an 18-year-old man with lymphoma of bone. Note the lytic destruction with extensive periosteal reaction. C: Radiographs of the left distal femur 5 years after treatment with radiation and chemotherapy.

The overall survival rate of patients with primary bone lymphoma is 58% at 5 years and 53% at 10 years. Metastasis or recurrence may occur many years later, making 5-year survival values less reliable. The clinical staging of lymphoma has important prognostic significance.

CHORDOMA

CLINICAL FEATURES

Chordoma is a rare malignant bone tumor that occurs in the midline of the axial skeleton. It is a lesion that originates from primitive notochord remnants and accounts for 1% to 4% of primary osseous malignancies. It arises primarily at the cephalad and caudad regions of the spine, with the remainder within the cervical, thoracic, and lumbar vertebral bodies. Sacrococcygeal lesions comprise 50% of the tumors. The vast majority of sacral lesions present in patients between 50 and 70 years of age and are extremely unlikely in those younger than 30 years of age. Chordomas are slow-growing, locally invasive tumors, but they metastasize in 10% of patients. Symptoms depend on the location. The lesions arising at the base of the skull present a decade earlier than their sacral counterparts because they have less space to grow before causing symptoms. Vertebral chordomas cause symptoms as a result of pressure on nerve roots or the spinal cord. Patients may have numbness in an extremity, followed by pain. Many develop motor weakness, and paralysis is a late complication. The sacrococcygeal lesions can become quite large before discovery and may be associated with a long history of vague lower back pain. This may be referred to the hip or knee with further neoplastic progression. The mass usually displaces but does not invade the rectum and may cause constipation. Bladder symptoms such as urinary frequency are common, and incontinence is a late finding. If the chordoma originates caudal to the S-1 level, there is rarely any sensory or motor disturbance to the lower extremities. Late in the course, pain may become severe and intractable. Sacral lesions often arise as a fixed, palpable presacral mass noted on rectal examination.

PATHOLOGIC FEATURES

On gross inspection, a chordoma may be lobulated and deceptively well circumscribed, but the tumorous tissue often extends beyond visible boundaries. It is soft, gray, and has a gelatinous consistency. Translucent areas may give it the appearance of a chondrosarcoma or mucinous carcinoma. The tumor can be focally cystic or hemorrhagic. The periosteum of the affected bone may be elevated, and a large soft-tissue mass is common.

Figure 128.20. (See Color Fig. 128.20.) Typical appearance of chordoma. The tumor is divided into lobules with fibrous septa. Tumor cells float in a blue myxoid background.
Microscopically, the tissue resembles fetal notochord. Lobules are separated by fibrous septa. Abundant basophilic extracellular matrix contains mucin and stains positively for glycogen. The cells are arranged in cords rather than being isolated in individual lacunae. Occasional islands of bone or cartilage are visible. On higher magnification, the cells are noted to be of various sizes and shapes with indistinct boundaries. The most classic type, called a phalaliferous cell, has a round nucleus with multivacuolated cytoplasm, giving it a bubbly appearance. The vacuoles may displace the nucleus to the periphery of the cell. The differential diagnosis includes liposarcoma, metastatic carcinoma, and myxoid chondrosarcoma.

**RADIODRAPHIC FEATURES**

The plain radiographic hallmark of a chordoma is midline bony destruction with a large associated soft-tissue mass (Fig. 128.21). The anterolateral mass is usually more extensive than the bony involvement. The lesions are poorly marginated and may be difficult to discern in the sacrococcygeal region. In the vertebral body, the chordoma is lytic, centrally located, and slowly expansive. Areas of sclerosis due to reactive bone formation are seen. Adjacent vertebral bodies and the intervening disc space can be involved.

![Figure 128.21](image)

Reports vary as to the activity of a chordoma on bone scan, and accumulation of isotope in the bladder can obscure the sacral area. CT scans and MRI have been extremely helpful in determining the extent of the lesion and determining its proximity to vital structures. This is essential in preoperative planning. CT scans identify calcified areas that are not evident on plain films. Along with myelography, CT is helpful in planning resection of a vertebral lesion. MRI is useful in discovering recurrent nodules after surgical resection. Angiography is only occasionally indicated to identify the proximity of a cervical chordoma to the vertebral arteries. The radiographic differential diagnosis includes metastatic disease, multiple myeloma, giant cell tumor, and neurogenic tumors.

**TREATMENT**

After discovering a midline destructive lesion thought to be a chordoma, perform a biopsy after all staging studies are completed. A posterior needle biopsy can be used in collaboration with an experienced bone pathologist. On the other hand, most biopsies are performed through an open posterior approach. Under no circumstances should a transrectal biopsy be performed due to contamination of intervening tissue planes.

The mainstay of treatment and best hope for long-term survival is *en bloc* resection of the tumor with a wide margin and a surrounding cuff of normal tissue (Fig. 128.21). This resection is easier to perform in sacrococcygeal lesions because the anatomy of the skull base often precludes complete excision (48,165). The sacral nerve roots must be sacrificed, if necessary, to obtain an adequate margin. Given the large size, poorly accessible location, and tendency to adhere to the bowel, a wide margin is difficult to achieve, so a marginal resection is often the best that can be done. There is a high recurrence rate with inadequate resection, and recurrent lesions carry a poor prognosis because they often infiltrate the surrounding tissues.

Preoperatively, perform a complete bowel preparation and intravenous antibo prophylaxis to decrease the chance of wound infection. Intraoperatively, suture the anus to prevent possible fecal contamination of the surgical field. Close the wound primarily only if this can be done without undue tension. The operative time can be prolonged with difficult resections; therefore, attention to blood loss is critical. Greater blood loss can be expected in higher sacral lesions from the middle sacral vessels and branches of the internal iliac veins. Control hemorrhage by ligation of one or both of the internal iliac vessels, particularly in lesions above S-3. Postoperatively, administer antibiotics and provide prophylaxis for deep venous thrombosis. Resection of lesions below the third sacral level can be accomplished through a posterior approach, as described by MacCarty and colleagues (84; see also references 29 and 63). Lesions more cephalad often need a combined anterior and posterior approach in the same operative setting. For high sacral lesions, sacrifice of involved nerve roots and plans for a colostomy should be anticipated. Surgical resection in this location is associated with high morbidity. Full sacral resection can be performed when necessary to achieve a wide margin. Current advances in skeletal reconstruction can maintain stability after extensive resections (see Chapter 126). Thoracic lesions should be approached via thoracotomy, although combined anterior and posterior reconstruction and stabilization is often required after vertebral body excision. A retroperitoneal approach is usually adequate for midlumbar to lower lumbar lesions.

Chordomas are generally radioresistant, but adjuvant treatment has been used for contaminated surgical margins or surgically inaccessible lesions. Given the increased recurrence rate of large lesions, attention has focused on new preoperative and postoperative irradiation approaches to improve the chance of local control (125,145). The amount of irradiation is limited by the sensitivity of the spinal cord in the cranial and cervical regions and by the pelvic organs, colon, rectum, and overriding sacral skin in more caudal lesions. To facilitate the use of high local radiation doses without structural damage, proton beam and photon beam radiation techniques have been successful, but their long-term effectiveness is yet to be established (145). Wound healing problems contribute to high morbidity after radiation therapy. In addition, there have been reports of postirradiation high-grade sarcomas after treatment of a chordoma (147). Although this is a rare occurrence, radiation therapy should not be routinely prescribed to all patients with this tumor without careful consideration. Chemootherapy has no current role in the management of chordoma.

**RESULTS OF TREATMENT**

In general, the results for long-term survival depend on the adequacy of the initial surgical resection. Multiple studies have shown increased rates of recurrence with intralesional margins compared with wide excision. One report showed an increased recurrence rate from 28% after *en bloc* resection of a chordoma to 64% if the tumor was exposed during resection (20).

Function after surgery depends on both the level of resection and on which sacral roots remain. If the S-1 level is preserved, loss of motor function is minimal (71). Stener and Gunterberg (143) reported on extirpation of high sacral tumors that no deficit of ureteral or anorectal function occurs if there is only unilateral sacrifice of all sacral nerves. If only the first sacral roots are preserved, no sphincter control will remain, and the patient will need routine bladder self-catheterization. If bilateral S-2 roots are maintained, up to 50% of patients may retain partial bowel and bladder control with need for catheterization. If at least one S-3 root is saved, sphincter control will be intact. Conversely, if the tumor is left untreated, 100% of patients will eventually have complete incontinence. Reconstruction is not needed if pelvic continuity can be maintained through preservation of half of the first sacral body (143).

A recent study examined 21 cases of sacrococcygeal chordoma (127). All lesions were approached posteriorly, and 14 had adjuvant radiotherapy. Four patients died, and 15 of the remaining 17 were disease-free at average 4.5-year follow-up. There was a 19% local recurrence rate, which compares well with the available literature, especially because a combined operative approach was used. It was suggested that preoperative or postoperative radiation therapy allowed a better result after a marginal resection. There was a 5% incidence of metastases at 5 years, which increased to 50% at 10 years.

Another study reviewed 47 patients who had a reaction of sacrococcygeal chordomas with a 9-year average follow-up (24). Eighty-one percent were approached posteriorly, and only 19% were resected with a wide margin. Fifty-two percent received adjuvant postoperative irradiation. The cumulative probability of local recurrence was 51% at 5 years and 75% at 10 years. When the lesion extended to the S-1 level, there was 100% recurrence in seven cases. There was a 24% probability of...
metastases at 5 years and 58% at 10 years. All but one patient with distant metastases also had local recurrence.

Chordomas are known to metastasize late, with the likelihood ranging from 5% to 40% in the literature. They can be found from 1 to 16 years after initial diagnosis. This finding is limited to sacral, or less likely vertebral, chordomas; the intracranial types rarely metastasize. Accurate prediction of which tumors will metastasize is not yet possible. The spread is to the regional lymph nodes, as well as the skin, lung, liver, and bone. Almost all patients die as a result of complications from local treatment failure rather than metastases, which are commonly asymptomatic. Studies show survival of patients with chordoma to be 45% to 77% at 5 years and 28% to 50% at ten years.

ADAMANTINOMA

CLINICAL FEATURES

Adamantinoma is an extremely rare primary malignant bony neoplasm. Half of the lesions occur in the second and third decades, and the remainder present throughout life. There is a slight male predominance. Ninety percent are found in the diaphysis of the tibia. Ten percent of patients have an ipsilateral fibular adamantinoma. The etiology of these tumors is not clear. They may have their origin in cells capable of differentiating into either epithelial or mesenchymal components, or else they are primarily an epithelial malignancy with a reactive fibrous stroma.

An adamantinoma presents as swelling with or without pain. It is a slow-growing lesion, and symptoms may be present from a few weeks to 50 years. More than one third of patients have symptoms for more than 5 years before diagnosis. A mass is the only finding on physical examination. An associated local traumatic event occurs in half of the patients, but no causal effect has been documented. There is slow but progressive bony destruction throughout adulthood. Metastases occur late, most often to the lungs, and account for 70% of the reported deaths from adamantinoma.

Adamantinoma is often confused with osteofibrous dysplasia, a benign tumor that presents in a similar location. However, the clinical presentation of osteofibrous dysplasia is in the first decade and generally asymptomatic. It is a self-limited process that does not progress or metastasize.

PATHOLOGIC FEATURES

Grossly, an adamantinoma can be firm or soft, granular or fibrotic, or smooth or lobulated. It is grayish white and may have areas of necrosis, hemorrhage, or cystic spaces. It is well marginated and easily distinguishable from the surrounding normal tissue. Most are greater than 5 cm in length and can often involve the entire tibial shaft.

Histologically, an adamantinoma has a biphasic appearance with epithelial and fibrous areas. There are multiple appearances of the epithelial components in the adamantinoma; however, all of the epithelial cells stain strongly for keratin. Disorganized bony fragments may be seen within the stroma. The stroma can look strikingly similar to fibrous dysplasia. The nuclei are bland with minimal atypia in only 15%. Usually, no mitotic figures are seen, but they can be present without causing alarm. Electron microscopy and immunohistochemical staining for cytokeratin or other epithelial markers will confirm the lesion as an adamantinoma. The histologic differentiation includes metastatic carcinoma, vascular neoplasms, synovial sarcoma, and osteofibrous dysplasia.

RADIOGRAPHIC FEATURES

Plain radiographs are characteristic, demonstrating lobulated, lytic areas surrounded by sclerotic reactive bone. A “soap bubble” appearance is classically described, with the tumor centered in the diaphysis of the tibia and asymmetrically expanding the anterior cortex. The lytic areas are sharply defined and may extend into the metaphysis but never occur in the epiphysis. Penetration of the cortex occurs in 15% of cases. Although there is a dominant central lesion, the eccentric lucent areas can occur throughout the shaft, separated by areas of sclerosis and having a multiloculated appearance. There may be bowing of the tibia in longstanding lesions. A bone scan is usually intensely positive because of the extensive bony reaction, but no uptake is seen past the edges of the lesion as defined on plain films. CT scans demonstrate whether or not the cortical lesion has penetrated into the soft tissues or medullary canal. MRI scans do not aid in the diagnosis but are valuable for preoperative planning. The radiographic differential diagnosis includes metastatic carcinoma, vascular neoplasms, synovial sarcoma, and osteofibrous dysplasia.

TREATMENT

Surgery is the primary method of treatment for adamantinoma. In the past, the malignant potential of this tumor was underestimated, and numerous cases were treated by local excision or curettage. This approach is associated with a 60% chance of local recurrence. It is now recognized that a wide margin is required by resection or amputation. All of the satellite lesions must be removed to minimize recurrence. Reconstruction after resection of a tibial lesion can be achieved by using intercalary allografts or vascularized fibular bone grafts. If the entire shaft is involved, wide resection may not be practical, and amputation may be necessary. Amputation is also considered for recurrent lesions or those with extensive soft-tissue involvement when a wide margin cannot be obtained. Mankin and colleagues described excellent early results after treatment by large segmental tibial resection followed by intercalary allograft replacement. Adjuvant radiation or chemotherapy has no role in the initial management of adamantinoma.
RESULTS OF TREATMENT

In an excellent review of all documented cases of adamantinoma by Moon and Mori (100), the mortality rate was 18%, and known metastases were present in 70% of the patients who died. Metastases develop in 15% to 20% of patients and are more common following an incomplete initial resection with recurrent disease. Given the slow-growing nature of this tumor, an aggressive approach to pulmonary or lymph node metastases is warranted. Local recurrence and metastases may occur months to decades after treatment of the primary lesion; therefore, long-term follow-up is necessary (50). It is important not to underestimate the malignant potential of this tumor. Strict adherence to the principles of oncologic surgery ensure an optimal result.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

EVALUATION OF THE PATIENT WITH A SOFT-TISSUE MASS

In stark contrast to bone tumors, soft-tissue masses of the extremities are a common physical finding. Whereas most are posttraumatic or inflammatory in nature, a certain number later prove to be benign or malignant soft-tissue neoplasms. Soft-tissue masses present a diagnostic and therapeutic challenge to the treating surgeon. Some require only observation, whereas others should be imaged with appropriate methods and subsequently undergo pathologic evaluation. The difficulty is knowing what features of the patient's soft-tissue mass—for example, size, depth, or texture—are important in differentiating benign from malignant disease. A consistent, comprehensive, and educated approach to the evaluation and treatment of a soft-tissue mass will allow the surgeon to overcome this difficulty and provide optimal care as well as avoid an inaccurate diagnosis and excessive or inadequate treatment.

HISTORY

Unfortunately, the patient's medical history is rarely of value. Cognitive and emotional issues, especially anxiety, denial, or ignorance, often cloud a patient's memory and reporting of events related to the tumor. Patients usually are unable to give an accurate estimate as to how long the mass has been present or its growth characteristics. Often, there is a history of trauma to the region that has brought the mass to the patient's attention. Symptoms may or may not be present in both malignant and benign tumors; however, you are more likely to investigate and eventually treat masses that are symptomatic.

A patient's medical history rarely gives keys to the diagnosis, except for patients with multifocal disease or those who have an established clinical syndrome. Exceptions include a familial history of lipomatosis, neurofibromatosis, Gardner's syndrome (colonic polyposis and desmoid tumor), Li-Fraumeni syndrome (familial breast cancer and soft-tissue sarcoma) (16), and Maffucci's disease (hemangiomas noted in conjunction with multiple bone enchondromas).

EXAMINATION

Similarly, physical findings are rarely accurate or diagnostic. Tumor size, depth, and consistency can only be approximated in all but very small subcutaneous masses. It is uncommon for a mass to be pulsatile, indicating an underlying vascular neoplasm, or for Tinel's sign to be present in association with peripheral nerve sheath tumors. Because of these factors, the difficult part of the evaluation of a patient with a soft-tissue mass is discerning which lesions should simply be observed and which should undergo further evaluation with imaging studies and possible biopsy. A suggested strategy is delineated in Figure 129.1 (13). As can be seen, tumor size and tumor depth are important features (18,24). Large or deep tumors should be considered malignant until imaging studies or biopsy prove otherwise.

IMAGING STUDIES

Radiographs for soft-tissue masses, unlike bone tumors, are rarely diagnostic. Occasionally, a relative radiolucency is seen in the soft tissues compared with the surrounding tissues. This would suggest the presence of fat and an intramuscular lipoma. Phleboliths may be seen with hemangiomas; however, other forms of mineralization in the form of calcification or ossification are nonspecific and may suggest either underlying myositis ossificans, atypical infection (parasitic), or synovial sarcoma.

An ultrasound examination of the mass is particularly helpful in locations about joints (ganglion or popliteal cysts) and in the evaluation of the fluid content of a soft-tissue mass. Purely cystic masses are not likely to be malignant. Ultrasound is also useful in guiding the performance of an aspiration or biopsy, with cyst contents
sent for cytologic evaluation.

Small masses (smaller than 5 cm) that are superficial can be observed at intervals of several months to detect any change in size. Even if the underlying lesion proves to be malignant, the prognosis for survival as well as for local control is excellent (20,30). If the mass grows or symptoms develop, perform a magnetic resonance imaging (MRI) scan, followed by biopsy and possible excision.

Obtain an MRI of deep, larger masses (more than 5 cm) of the extremities. If the mass has signal characteristics identical to those of subcutaneous fat on all sequences, it does not enhance with gadolinium, it is most likely to be a lipoma. Heterogeneous, large, or deep masses, especially those with a low signal on T1-weighted images and a higher signal on T2-weighted images, or those with gadolinium enhancement, should be suspected to be soft-tissue sarcomas. Additional imaging tests may be indicated, depending on the clinical diagnosis. Note that any local imaging study will have real and artificial changes introduced by the performance of any operative procedure, including a biopsy; this will make their interpretation difficult. Therefore, perform all local imaging studies before any operative intervention.

Computed tomography (CT) useful in identifying the location of soft-tissue tumors in the extremities but is more valuable in the pelvis. In many cases, CT scans reveal the proximity of the tumor to bone, nerve, and vascular structures; they also accurately indicate fat density. Lipomas usually can be differentiated from other tumors. CT scans are also important in the staging of malignant soft-tissue tumors in that the most common site of metastases from soft-tissue sarcomas is to the lungs. In comparison to plain radiography, CT has superior resolution in the imaging of metastatic disease in the lungs. Perform a CT scan of the retroperitoneum in the evaluation of extremity myxoid liposarcomas because, on occasion, patients will have concomitant disease in the retroperitoneum and extremities.

**BIOPSY**

Biopsy is the final step in the evaluation of a patient with a soft-tissue mass. The biopsy is a technically simple procedure, but it requires extensive training and experience. A well-planned and executed biopsy provides an accurate diagnosis and facilitates treatment. A poorly performed biopsy, on the other hand, may fail to provide a diagnosis and, more important, may have a negative impact on patient survival and treatment options, especially the potential to preserve a limb (17). For these reasons, if a soft-tissue mass may be malignant, the biopsy should be performed by the surgeon who will ultimately be responsible for the full care of the patient.

**Open Incisional Biopsy**

Open incisional biopsy is a reliable means of making the diagnosis in soft-tissue tumors. Make the incision as small as is compatible with obtaining an adequate specimen notch.

- Perform the biopsy through a longitudinal incision. In the operative dissection, do not expose or contaminate important vascular or neural structures. Do not violate anatomic compartments other than those containing the tumor.
- Take special care around joints to prevent intraarticular contamination with tumor cells.
- Biopsies of soft tissue should not involve major tendons (e.g., the patellar tendon) or their insertion.
- In a biopsy, do not use intramuscular or intravenous planes, as in more standard orthopaedic approaches. Instead, use a direct approach with the smallest possible incision directly through skin, subcutaneous tissue, fascia, and muscle down to the tumor.

**Fine-Needle Aspiration**

Pathologic diagnosis of a soft-tissue mass based on fine-needle aspiration is based on a pathologist's cytologic interpretation of single cells aspirated through a 0.6 to 1.0 mm—diameter needle. Fine-needle aspiration is more accurate in diagnosing homogeneous tumors than inhomogeneous tumors. If the mass grows or symptoms develop, perform a magnetic resonance imaging (MRI) scan, followed by biopsy and possible excision.

- After preparation of the skin, use the needle to make serial aspirations of the tumor bed through a single entry site. This site is agreed on by both the surgeon and the pathologist; ideally, mark it with any method that will allow future identification.
- This specimen is prepared immediately by the cytology technician, and the tissue is fixed according to the cytologist's preference. Often, the slides can be evaluated immediately.
- Maintain pressure on the biopsy site so that hematoma formation is minimized.

**Tru-cut Needle Biopsy**

A Tru-cut (Baxter Health Care Corporation, Valencia, CA) needle biopsy is a trephine biopsy in which a 14-gauge cannula and trocar system are used that allow cores (approximately 1.75 mm) of tissue to be obtained with preservation of the architecture of the specimen.

- After preparation of the skin and infiltration with local anesthesia, use a #11 blade to incise the skin 2 to 3 mm.
- Then place the Tru-cut needle into the tumor bed. It is helpful to introduce the Tru-cut with the outer cannula sheath retracted, exposing the inner trocar tip and specimen notch.
- Sharply advance the outer cannula once the needle tip is placed within the tumor mass itself, so that an inner core of tissue is trapped.
- Repeat this procedure until multiple cores are available for pathologic review.
- Process the specimens with formalin in formalin or in glutaraldehyde.
- Maintain pressure on the site for several minutes to minimize hematoma formation.

An accurate diagnosis is obtained in approximately 80% of soft-tissue masses undergoing a Tru-cut biopsy (29).

**Open Incisional Biopsy**

An open, incisional biopsy is a reliable means of making the diagnosis in soft-tissue tumors. Make the incision as small as is compatible with obtaining an adequate specimen notch.

- Proceed sharply through subcutaneous fat, fascia, and muscle. For intramuscular tumors, a color change in muscle from red to salmon often heralds the approaching tumor pseudocapsule. Malignant tumors are usually gray or white.
- Sample diagnostic tissue at the periphery of the tumor, which typically is the most viable region. A biopsy of necrotic appearing tissue is usually not of benefit.
- Perform frozen sections in all cases, if possible, for confirmation of the presence of tissue from which the pathologist may make a diagnosis. This is true even if definitive surgery is not planned at the same time.
- Meticulous hemostasis is essential so tumor spread by hematoma is prevented.
■ Drains may be used, but they should be placed close to and in line with the incision to allow the future excision of the drain site along with the biopsy site. An outside-in technique for introduction of the drain, when the drain site is made with a scalpel and the drain is placed retrograde into the wound, is preferable to the use of a trocar from the deeper wound through the skin.

■ Caution: Do not use widespread infiltration of local anesthetic or place sutures at a distance from the wound. A tourniquet may be applied for the procedure, but it must be deflated before wound closure. Do not exsanguinate the limb before biopsy.

■ As with all surgical procedures, minimize postoperative limb swelling, edema, and bleeding through the use of sterile compressive dressings. Limb immobilization and elevation may also be required.

OPERATIVE PLANNING

The decision to proceed with operative resection and the specific type of procedure performed depend on many factors, including the diagnosis, the local and distant extent of disease, the tumor location, the functional consequences of resection, and the patient's symptoms. An estimation of the growth pattern and malignant potential of the tumor will ultimately dictate treatment. Some benign tumors (e.g., lipomas) grow slowly in a centrifugal fashion and are bounded by surrounding anatomic structures such as fascia, bone, nerve, or vessels. A compressed area of fibrous adventitial and vascular structures forms a true capsule surrounding these neoplasms. In contrast, other benign tumors, such as intramuscular hemangiomas or desmoid tumors, lack a true capsule and often have permissive and infiltrative borders. Even malignant soft-tissue tumors, at least early on, respect anatomic borders but, instead of a true capsule, are surrounded by a "pseudocapsule" or reactive zone (7). This zone and the area surrounding it contain microscopic extensions or satellites of malignant tumor. An understanding of the growth characteristics is important in the selection of the most effective operative procedure for obtaining local control.

Enneking et al. (7,8) defined surgical resections as intralesional, marginal, wide, or radical.

■ An intralesional resection is performed within the reactive zone of the tumor and includes debulking procedures. This form of resection is likely to leave both macroscopic and microscopic residual disease and to be associated with a high incidence of local relapse. This procedure is indicated for many benign tumors, but it is associated with an unacceptable risk of local recurrence in the case of malignant tumors because of residual microscopic peripheral satellite disease. For this reason, in the treatment of sarcomas, an effective adjuvant, most often radiation therapy, is administered in combination with a marginal operative resection for obtaining local control.

■ A wide resection, performed within normal tissue peripheral to the reactive zone, is preferred for a soft-tissue sarcoma. With modern imaging for accurate determination of the tumor extent, this operative procedure is associated with a low incidence of local relapse and is recommended for most infiltrative benign and malignant tumors.

■ A radical resection is one in which the entire anatomic compartment of tumor origin is removed. This procedure carries little, if any, advantage over wide resection in minimizing the prevalence of local recurrence and is now only rarely performed.

Amputations performed for malignant soft-tissue tumors may also be defined as marginal, wide, or radical according to the above-mentioned definitions. The indications for amputation are sepsis, extensive contamination of tissue from hemorrhage, a poorly performed biopsy, or extensive tumor involvement of vital neurovascular structures. Amputation may also be considered when the functional results after an ablative procedure would be superior to those following resection and adjuvant therapy. Additional indications may be the presence of multifocal disease, intractable pain, or local relapse.

Suggested resections for selected diagnoses are indicated in Table 129.1.

The diagnosis, the anatomic location of the tumor, and the functional consequences of resection determine the operative strategy. Asymptomatic benign tumors may be treated nonoperatively in an area where function after surgery is likely to be compromised. Benign tumors in easily accessible sites are often removed even in the absence of symptoms. For sarcomas located in the distal leg or foot, amputation may be preferable for tumor control, given the relatively good function and oncologic results after distal lower extremity amputations. A malignant tumor adjacent to a major nerve or artery may dictate that a marginal resection, in addition to some form of adjuvant therapy, be administered.

The extent of disease at the time of diagnosis influences the surgeon's decision as to what procedure to perform. In patients with malignant disease, it is important to determine the local and distant extent (metastases) of the tumor. Soft-tissue sarcomas most commonly metastasize to the lungs, and chest radiography and CT are indicated as a part of the initial evaluation. Metastases to lymph nodes and bone are unusual, and the additional value of technetium bone scanning, gallium scanning, or positron-emission tomography (PET) scanning is not clear. Adults with metastatic soft-tissue sarcomas at the time of diagnosis, or with severe comorbid medical conditions, have a very poor prognosis, and surgery may not be indicated except for palliation. Similarly, in some benign tumors, such as plexiform neurofibromas or extensive intramuscular hemangiomas, the tumor may be so extensive locally that resection would be associated with severe functional disability. In such cases, it may be in the patient's best interest not to attempt to resect all disease.

SURGICAL TECHNIQUES

WIDE EXCISION OF A SUBCUTANEOUS SARCOMA

Approximately one third of all soft-tissue sarcomas are located subcutaneously (25). Most are small (smaller than 5 cm) and are presumed, before operative resection, to be benign neoplasms. Therefore, most subcutaneous sarcomas are referred to surgical oncologists after excision. On reexcision of the tumor bed, focal residual sarcoma has been noted in more than one half of the patients treated (12,20). For this reason, surgical reexcision of the operative field is recommended in the treatment of patients with subcutaneous sarcomas. With such treatment, excellent rates of local control can be obtained (10).

A wide margin for subcutaneous sarcoma is defined as a normal cuff of skin and subcutaneous fat in continuity with fascia and muscle. Because there is no anatomic barrier to the spread of a subcutaneous sarcoma, the surgeon must determine, by palpation and careful review of imaging studies, the extent of a resection that will be necessary to encompass the entire previous operative field while remaining in normal tissue. Fortunately, in a subcutaneous location, major neurovascular structures are rarely involved.

For a wide excision, resect an area of skin approximately 3 to 5 cm about the biopsy site, as well as any obvious hematomas (Fig. 129.2).
Enzinger and Weiss have defined soft-tissue tumors as “non-epithelial extra-skeletal tissue of the body exclusive of the reticuloendothelial system, glia, and supporting tissue of various mesenchymal organ” (9). Benign soft-tissue neoplasms are believed to be at least 100 times more common than their malignant counterparts.
soft-tissue sarcomas. Soft-tissue sarcomas may arise in any part of the body but are most common in the extremities, specifically the thigh and buttock. Common benign deep soft-tissue tumors include intramuscular lipomas, extraabdominal fibromatosis (desmoid tumors) hemangiomas, and benign nerve sheath tumors.

CLASSIFICATION

In contrast to previous systems in which tumors were believed to arise from normal cells of a similar histologic appearance, the current histologic classification of soft-tissue tumors is based on the apparent differentiation of the tumor cell. Most tumors arise from an undifferentiated precursor cell and acquire phenotypic traits of various normal cells during neoplastic transformation. It is this appearance by which the tumors are classified rather than by the tissue of origin. The tumors are classified as benign, intermediate, or malignant based on their perceived capability of metastasis. Malignant tumors are subcategorized as low grade or high grade based on their histologic characteristics including tumor necrosis, cellular anaplasia, and the number of mitotic figures. Patients with high-grade tumors are at an increased risk for developing metastatic disease compared with those with low-grade tumors.

The most common soft-tissue tumors are noted in Table 129.2. This table is based largely on the classification of soft-tissue tumors by the World Health Organization, with subsequent modification as described by Enzinger and Weiss. Again, this classification of tumors does not imply that the histologic appearance of the tumor is related to the tissue of origin. In addition, one must be careful not to assume that malignant soft-tissue tumors of one histologic type are the result of malignant degeneration of a benign neoplasm. Malignant degeneration of an underlying benign soft-tissue neoplasm is very rare.

Table 129.2. Histologic Classification of Soft-Tissue Tumors11

FIBROUS LESIONS
These spindle cell neoplasms whose histologic appearance resembles fibrous tissue are common and may be reactive (nodular fasciitis), benign (fibroma of tendon sheath), infiltrative (desmoid tumor), or malignant (fibrosarcoma). Fibrous neoplasms of infancy and childhood should be considered separately because of their unique and often self-limiting behavior.

Nodular Fasciitis
Nodular fasciitis is a benign proliferation of fibroblasts often mistaken for a malignant soft tissue tumor because of its rapid onset of growth, mitotic activity, and cellularity. It is most likely a self-limiting reactive process rather than a true neoplasm. Most patients present with a rapidly growing mass with associated tenderness. It is often located in the upper extremities, especially in the volar aspect of the forearm. In infants and children, it may be found in the head and neck region. It is usually small (smaller than 5 centimeters). It may be subcutaneous, intramuscular, or fascial based. It is usually treated by marginal excision and has a low recurrence rate (4). Spontaneous regression has been observed.

Palmar Fibromatosis
This condition is known as Dupuytren's disease or Dupuytren's contracture and is the most common type of fibromatosis. Its etiology is unclear. It is seen most commonly in people older than 65 years of age. It may be associated with other forms of fibromatosis including plantar fibromatosis and penile fibromatosis (Peyronie's disease). It is also noted to be of increased incidence in patients with epilepsy and diabetes. It has also been known to be associated with chronic alcoholism and liver cirrhosis.

The onset of the disease is slow and insidious. Often, a firm nodule is palpable in the palmar aspect of the hand affecting the ulnar aspect of the hand. It may be associated with joint contracture. A single small nodule or an ill-defined conglomerate of several nodules is found on examination. Pathology consists of spindle-shaped fibroblasts and variable amounts of dense collagen. Treatment may include nonoperative therapy including physical therapy and topical treatment, but rarely do these measures have a significant effect on the disease. Operative resection, however, remains the treatment of choice in the patient with impairment secondary to flexion contractures of the digits. Fasciectomy is usually recommended as the treatment of choice (23). Local recurrence may result in recurrent contracture.

Plantar Fibromatosis
This disease is similar to palmar fibromatosis and is identified by nodular fibrous proliferation arising with the planar aponeurosis. Unlike disease in the hand, it is usually not associated with contractures of the digits. Usually, a single subcutaneous thickening or nodule that adheres to skin and is located in the middle or medial portion of the foot is found on examination. It may be painful and may be bilateral. The lesion is more common in men than women. It occurs in younger individuals than palmar fibromatosis. Pathologic findings are identical to palmar fibromatosis. Treatment is directed at the patient's symptoms, and nonoperative therapy consists of shoe pads and modified shoe wear. Radical fasciectomy is considered for patients with intractable pain but is associated with local recurrence in a number of cases (6).

Desmoid Tumor
Desmoid tumor or extraabdominal fibromatosis is a difficult problem for those caring for patients with soft-tissue neoplasms. It has the potential to obtain a large size, often recurs despite operative resection, and is infiltrative in nature. It may be associated with colonic polyposis (Gardner's syndrome). Clinical findings are usually a soft-tissue mass in the young adult. It is common to see the shoulder, flank, and the muscles of the thigh. It may be multifocal within an extremity. Histologically, fibromatosis is benign in appearance with spindle-shaped fibroblasts and dense collagen. Imaging studies reveal that the tumor is typically of low signal on both T1- and T2-weighted images because of the large collagen content. Operative resection is considered for tumors in expendable locations (3). However, despite complete surgical resection, it is associated with recurrence in a number of cases. Adjuvant treatment in the form of radiation therapy is often considered for these individuals. Medical treatment in the form of estrogen blockade or chemotherapy may be considered in selected circumstances.

Fibrosarcoma
Fibrosarcoma is a malignant tumor of soft tissue whose cells resemble fibroblasts but with significant cellular atypia, frequent mitoses, and increased cellularity compared with its benign counterparts. Before the subclassification of malignant fibrous histiocytoma, fibrosarcomas were the most common soft-tissue malignancies. Fibrosarcomas are often low grade. The recommended treatment is wide resection or marginal resection combined with adjuvant radiation therapy.

Malignant Fibrous Histiocytoma
This tumor is composed of cells characterized by a storiform or cartwheel-type growth pattern. The actual histogenesis of the tumor may not be from a histiocyte but more closely related to the fibroblast. This tumor is also known as an adult spindle cell sarcoma. These neoplasms may be low grade or high grade based on their cellularity, atypia, and the presence or absence of mitotic figures and necrosis. They are commonly located in the subcutaneous tissue or the deep soft tissues of the thigh. Like other soft-tissue sarcomas, they are best treated with wide resection. Marginal resection can be combined with adjuvant radiation therapy. Patients with large, high-grade soft tissue sarcomas may, in addition, benefit from adjuvant chemotherapy (22).
LIPOMATOUS SOFT-TISSUE TUMORS

Lipoma

Lipoma is the most common soft-tissue tumor arising virtually anywhere in the body. The tumor is usually a soft, mobile, and asymptomatic mass with a very large range of sizes noted. The magnetic resonance images of a lipoma show signal characteristics similar to surrounding fat on all sequences. It is the one tumor that can usually be diagnosed by MRI. Asymptomatic lesions do not require treatment. Malignant transformation is rare. Symptomatic tumors are usually treated with local excision. Local recurrence is rare.

Liposarcoma

Liposarcoma is the second most common malignant soft-tissue tumor seen in the extremities. It is also very common in the retroperitoneum. Liposarcomas may be low grade or high grade. The characteristic cell is the lipoblast, which consists of a cell containing large amounts of clear cytoplasm but with several septated vacuoles that secondarily indent the nucleus. This is different from the signet ring cell, a cell with a large clear cytoplasm and a thinned eccentric nucleus at one pole. Signet ring cells can be seen in both benign and malignant lipomatous soft tissue tumors. The lipoblast is characteristic of a malignant tumor. Higher grade liposarcomas may be difficult to differentiate from other soft-tissue sarcomas such as malignant fibrous histiocytoma because of the dense cellularity obscuring those cells that resemble fat. It should be noted that liposarcomas do not have an appearance similar to lipomas on MRI, that is, they tend to be of low signal on T1-weighted images and of bright signal on T2-weighted images. The management of liposarcoma is identical to other soft-tissue sarcomas, that is, wide resection when possible or marginal resection with adjuvant radiation therapy. Unlike other soft-tissue sarcomas, however, liposarcomas (especially the myxoid type) of the extremity may be associated with disease in other, nonpulmonary sites (e.g., retroperitoneum) (21).

SMOOTH MUSCLE NEOPLASMS

Leiomyomas and Leiomyosarcomas

These are relatively infrequent soft-tissue neoplasms seen in the extremities. Benign neoplasms may be managed with marginal resection. Malignant soft-tissue sarcomas require wide resection or marginal resection and adjuvant radiation therapy.

STRIATED MUSCLE TUMORS

Rhabdomyoma and Rhabdomyosarcoma

These tumors are rare soft-tissue neoplasms. A benign rhabdomyoma is exceptionally unusual and of variable presentation. The diagnosis is usually made on the basis of an open biopsy. Rhabdomyosarcoma, although unusual, is the most common soft-tissue malignancy of children. When it is located in an extremity, it is often of the alveolar histologic type. The characteristic tumor cell of a rhabdomyosarcoma is the rhabdoid cell, which is a large, irregularly shaped cell with an eccentric nucleus and eosinophilic cytoplasm. These high-grade tumors are often associated with metastatic disease at the time of presentation and are treated with systemic chemotherapy (21). The role of operative intervention is unclear and controversial. Radiation therapy may be considered. These tumors may actually be more closely related to soft-tissue Ewing's or soft-tissue primitive neuroectodermal tumor.

VASCULAR NEOPLASMS

Hemangioma

Hemangiomas are benign neoplasms resembling normal blood vessels. Some actually represent vascular malformations rather than true neoplasms. They are often seen in infants and may spontaneously regress. They may be localized or multifocal, in which case they are known as angiomatosis (22). The majority of hemangiomas are superficial lesions with a predilection for the head and neck but may also occur internally. Tumors may be responsive to circulating hormones, and changes in size may be seen during pregnancy. Based on the histologic appearance, they are subclassified as capillary hemangiomas, which are often seen in children. Cavernous hemangiomas are large with thin-walled veins. Hemangiomas may be seen in conjunction with dyschondroplasia, also known as Maffucci's syndrome. When the tumor is located in a subcutaneous or dermal location, there are often characteristic color changes to the skin. There is no such skin change found with deeper situated tumors. Radiographs may demonstrate phleboliths within the lesion. Vascular studies and ultrasound may show vascular flow but may be difficult to distinguish from other vascular neoplasms.

The treatment of a localized hemangioma, as long as the diagnosis is known, is based on symptoms. Again, many grow slowly if at all. This is especially true in children, in whom lesions are often known to regress spontaneously. Localized disease may be marginally resected, with an approximate 20% local recurrence rate. More difficulties are encountered with the extensive hemangiomas and multifocal hemangiomas. Angiographic embolization has been used to treat many afflicted individuals with variable success. Radiation therapy has been considered in the past but should be used with great caution in young people.

Angiosarcoma

These malignant soft-tissue tumors resembling blood vessels are rare. Significant is the association of angiosarcoma with chronic lymphedema, for example, in patients following mastectomy and lymph node resection. Operative wide resection is the treatment of choice, and multifocal disease is commonly encountered.

SYNOVIAL NEOPLASMS

Tenosynovial Giant Cell Tumor

These tumors may be localized or diffuse and located in juxtaarticular or intraarticular locations. Intraarticular disease is known as pigmented villonodular synovitis and, again, may be localized or diffuse (27). Tenosynovial giant cell tumor affecting the tendon sheath is known as giant cell tumor of the tendon sheath. These tumors are believed to be benign neoplasms that may actually be reactive in etiology. Localized disease is usually treated with marginal resection. Diffuse disease, especially intraarticular disease in a large joint, such as the knee, may require synovectomy, and intraarticular or external beam radiation therapy.

Synovial Sarcoma

This is the third most frequently seen soft-tissue sarcoma in adults and the second most frequently seen soft-tissue sarcoma in children. It is typically not located within a joint but within the structures about a joint. Many are located in the hand or foot. These tumors may be monophasic or so-called biphasic, consisting of plump synovial cells arranged in a glandular pattern with other fibroblastic areas around it. Radiographs of these lesions may reveal mineralization in the form of calcification.

Like other soft-tissue sarcomas, MRI studies usually show predominantly low signal on T1-weighted images and bright signal on T2-weighted images. These lesions usually enhance with gadolinium infusion.

As with all soft-tissue sarcomas, operative treatment is wide resection or marginal resection and radiation therapy. Some synovial sarcomas may respond well to systemic chemotherapy (28).

NEURAL LESIONS

Neurofibromas

Neurofibromas are benign neoplasms noted in variable locations and may be solitary or part of a neurofibromatosis or von Recklinghausen disease (13). Often, this disease is noted as an inherited dominant trait of variable penetrance. It may be associated with scoliosis, congenital pseudarthrosis of the tibia or clavicle, and giantism. Neurofibromas are often asymptomatic. People with von Recklinghausen's disease may develop malignant nerve sheath tumors as well. Sarcomatous degeneration should be suspected in patients with very large or rapidly growing tumors.

In contrast to the neurilemmoma, which tends to be localized, neurofibromas are often extensive and infiltrative in nature around the nerve of origin. For this reason, if it
is decided to remove these tumors, it is often necessary to resect the underlying nerve. Operative resection, however, is only indicated for symptomatic lesions or for those suspected of sarcomatous degeneration.

Neurilemmoma

In contrast to neurofibromas, neurilemmomas are localized benign neoplasms that are often located within the nerve sheath itself. It is often a fusiform soft-tissue mass tapered at either end by the axons resuming their normal position within the nerve proximal and distal to the lesion. The MRI scan often shows that this tumor is of very bright signal on T2-weighted images and is usually homogeneous. Physical findings often reveal Tinel's sign or a radiating sensation with direct percussion. Marginal resections are associated with a low incidence of recurrence. Pathology reveals a biphasic appearance with compact (Antoni A) or densely cellular areas alternating with areas with relatively few cells (Antoni B). Small clusters of palisading cells around a central eosinophilic area are known as Verocay bodies. Operative excision is often carried out as a form of diagnostic biopsy in which the nerve sheath itself is split longitudinally in order to remove the lesion without harming the surrounding axons. It is usually encapsulated and freed relatively easily from the underlying nerve.

Malignant Nerve Sheath Tumors

These tumors are often high-grade large neoplasms. Their behavior, however, is not unlike other high-grade soft-tissue sarcomas (14). Operative treatment is preferably wide resection or marginal resection with adjuvant treatment.

STAGING OF MALIGNANT SOFT-TISSUE TUMORS

Systems have been developed for the staging of malignant soft-tissue tumors in an effort to predict the prognosis and evaluate the effect of therapeutic intervention by stratifying similar tumors according to various prognostic factors. Commonly used factors are tumor grade, size, compartmentalization of the tumor, and the presence or absence of metastases.

For soft-tissue sarcomas in adults, the two staging systems that are used at present were developed by the American Joint Committee on Cancer (AJCC; Table 129.3) (2) and by Enneking (Table 129.4) (5). In both systems, the variables used in the assignment of an appropriate stage include tumor grade, location, and the relative extent of the tumor, as well as the presence or absence of metastases.

Both systems agree that the presence of metastases is a very poor prognostic factor. This is true if metastases occur either to the lungs or to lymph nodes. The differences between the systems is that, first, the AJCC system is based on a grading system containing four variables, whereas the Enneking system considers only high and low grades. Second, the AJCC system uses tumor size as an important prognostic variable as opposed to compartmentalization of the tumor, and the presence of metastases.

The AJCC staging system uses tumor depth to be an important prognostic factor. This is true if metastases occur either to the lungs or to lymph nodes. The differences between the systems is that, first, the AJCC system is based on a grading system containing four variables, whereas the Enneking system considers only high and low grades. Second, the AJCC system uses tumor size as an important prognostic variable as opposed to compartmentalization of the tumor, and the presence of metastases.

The staging systems available are based on histologic and clinical observations, and they serve to guide therapeutic strategies. However, these systems are based on variables that are crude and of limited usefulness. New discoveries in the fields of molecular and cellular biology are being made and will be correlated with the clinical course and outcome. These findings almost certainly will change the manner in which tumors are classified and staged, and will predict more accurately the behavior of a given tumor in a particular patient. Operative treatment, chemotherapy, and radiation therapy can then be used in a rational and effective manner to improve the functional and oncologic outcome (19).

COMPLICATIONS

The complications of surgery to remove soft-tissue tumors are the same as those encountered for all orthopaedic surgery, as discussed in Chapter 5 and Chapter 8. The two most significant complications of the management of soft-tissue tumors of the extremities are improper performance of a biopsy, which leads to either misdiagnosis or compromise of the definitive method for surgical treatment, or recurrence after resection of an aggressive benign tumor or malignant tumor. Small benign-appearing tumors in the distal portions of the extremities are commonly removed by general orthopaedic and other surgeons by excisional biopsy with marginal resection. When histology reveals a malignant tumor, it is prudent to have the next stage of treatment management performed by an experienced oncology team consisting of a surgeon, medical oncologist, and radiation therapy specialist. In the case of lesions in which a malignant tumor is an obvious part of the prebiopsy differential diagnosis, biopsy should be performed only by a surgeon experienced in the treatment of malignant tumors who is prepared to carry out definitive treatment in conjunction with an oncology team. This approach will minimize the risk of local recurrence and enhance the long-term survival of patients with these troublesome tumors. In performing biopsy and subsequent resection of these tumors, the principles discussed in this chapter must be meticulously followed.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Metastatic bone disease is the most common cause of bone destruction in the adult skeleton. Each year in the United States there are approximately 1.3 million new cancer cases (10). The most common carcinomas, those of the breast, lung, prostate gland, and kidney, are also the most common cancers that metastasize to bone (9, 10, 11). The common distribution of bone metastases is to the spine, ribs, pelvis, and proximal limb girdles (1). Lung carcinomas and melanomas have the ability not only to occur in the axial skeleton but also to spread peripherally to the hands and feet (13, 14). It is important for the clinician to remember that virtually every known cancer may metastasize to bone and that any bone in the body can be involved.

The goals of treatment of primary bone sarcomas are to both achieve local control of the tumor and reconstruct a limb that will be functional. In contrast, the goals of treatment of patients with metastatic bone disease are to stop progression of the tumor, control pain, and maintain the quality of the remaining life of the patient.

Virtually all patients with metastatic bone disease will die of their cancer. Patients and their families greatly appreciate the clinician's expertise and commitment to maintaining the patient's independence in ambulation and the activities of daily living. Uncontrolled pain, confinement to bed, pathologic fractures, and neurologic compromise lead to despair and must be avoided.

The purpose of this chapter is to provide the clinician with a working knowledge of the evaluation, decision making, operative treatment, and postoperative care of the patient with metastatic bone disease.

EVALUATION

Bone pain is common in cancer patients. Carefully evaluate the patient to determine the source of the pain and to plan treatment. The essential steps in evaluation are history, physical examination, and plain radiographs (11).

Take a careful history. Determine the nature of the patient's pain. Pain at rest; severe pain; pain not responsive to anti-inflammatory medications and narcotics such as Tylenol with codeine, Tylox, and Darvocet; and pain at night are common complaints of patients with bone metastases. The pain often begins as a dull ache and then becomes constant. Activity-related pain is common with lower extremity metastases. Patients with lower extremity metastases will often relate a decrease in their ability to ambulate accompanied by fatigue, pain, and weakness. Patients with vertebral metastases often have pain and weakness, and they may have bladder and bowel dysfunction.

Patients with metastatic bone disease may have no prominent physical findings. Atrophy is common with lower extremity metastases, and the clinician can often elicit tenderness with deep palpation. Perform a careful neurologic examination of the upper and lower extremities. If the patient has back pain or reports bowel or bladder dysfunction, perform a rectal examination to exclude cauda equina syndrome.

Take plain radiographs in two planes of the painful areas. Many times, it is difficult to localize pain exactly in the upper extremity, back, or pelvis. In these areas, it is often necessary to obtain a combination of radiographs (Table 130.1). Carefully review the radiographs because the initial findings may be very subtle. The key features to look for are:

<table>
<thead>
<tr>
<th>Type of pain</th>
<th>Combination of radiographs</th>

</tr>
</tbody>
</table>

Table 130.1. Combinations of Radiographs for Bone Pain in Cancer Patients

1. Cortical bone destruction: In metastatic bone disease, one may see the bone destruction on the endosteal or periosteal surface.
2. Periosteal reaction: Small areas of periosteal reaction are often the only evidence that the tumor has left the medullary cavity.
3. Permeative pattern of bone destruction: In contrast to bone sarcomas, which cause large areas of cortical bone destruction, in metastatic bone disease there are often very subtle areas of permeative bone destruction in the cortex.
4. Destruction of the vertebral pedicle: In the spine, the cortical destruction in the pedicle is an early radiographic sign of metastatic bone disease. This finding is often subtle and must be looked for carefully.

CLINICAL SCENARIOS

After completing the initial history, physical examination, and plain radiographs, there are generally four different clinical scenarios:

1. Patients with advanced metastatic disease, including diffuse visceral and bone metastases. In this scenario, the orthopaedic surgeon is not called on to make a diagnosis but rather to evaluate and manage either a fracture or an impending fracture.
2. Patients with a history of cancer and a single destructive bone lesion. In this scenario, perform a very careful evaluation because you cannot simply assume that an undiagnosed bone lesion is necessarily related to the patient's prior cancer. Plan the evaluation as if you were evaluating the patient without the history of the prior cancer. The staging evaluation includes a technecium bone scan, chest radiograph, computerized tomographic (CT) scan of the chest and abdomen, and serum laboratory studies (complete blood count, erythrocyte sedimentation rate, chemistry group, and serum protein electrophoresis) (Table 130.2).

3. Patients without a history of cancer and a single destructive lesion. Many patients with metastatic bone disease present with a destructive lesion without a history of cancer. Skeletal pain or fracture heralds the presence of an occult primary malignancy (sentinel metastasis). A sentinel metastasis is common in carcinomas of the kidney, lung, and melanoma. The evaluation of the patient with a single destructive lesion is exactly the same as the scheme for the patient with a known cancer with a single destructive lesion.

4. Patients with a history of cancer, bone pain, and normal radiographs. Primary care physicians, medical and radiation oncologists, and orthopaedic surgeons often evaluate cancer patients with bone pain and normal radiographs. This scenario is tricky. Do a careful history and physical examination to avoid both undertreatment and overtreatment. If the plain radiographs do not show a destructive lesion, try to establish the cause of the pain. For example, if the patient has shoulder pain, look for a degenerative, traumatic, or other anatomic problems such as rotator cuff tendinitis, cervical spondylosis, acromioclavicular joint arthritis, and glenohumeral arthritis. If a reasonable working diagnosis cannot be established, then search for bone metastases with other imaging techniques. A technecium bone scan is very sensitive; it will detect an occult metastatic focus in about 85% of patients (23). Magnetic resonance imaging (MRI) is also highly sensitive and can pinpoint the site of the pain. If the patient's shoulder pain is secondary to a cervical vertebral metastasis, however, an MRI of the shoulder will not detect the lesion.

Rougraff, Kneisel, and Simon have developed a strategy to evaluate patients with an unknown primary tumor that has metastasized to bone (22). This plan is based on the knowledge that the two most common occult primary carcinomas that metastasize to bone are lung and kidney cancers. When one wishes to search for the occult primary malignancy, a CT scan of the chest is used to look for either a primary lung carcinoma and a CT scan of the abdomen, or abdominal ultrasound is used to detect a renal carcinoma. Serum studies are used to detect multiple myeloma. Patients with multiple myeloma have a decreased hemoglobin level or an increased erythrocyte sedimentation rate, or both, in approximately 60% to 70%. This simple staging evaluation identifies the primary carcinoma in up to 85% of patients. In contrast, biopsy of the bone lesion alone identifies the primary in less than 5% of patients.

If this staging study is negative, we generally do not pursue further tests such as gastrointestinal contrast studies or endoscopy. We designate the patient as having an unknown primary carcinoma.

**DECISION MAKING**

When faced with a patient with a destructive lesion, decide whether the patient should be treated with both surgery and radiation or radiation alone. Virtually all patients with complete fractures need surgery unless their medical condition is too precarious or their life expectancy is very short (less than 2 to 4 weeks). Fracture risk is multifactorial, and there are no absolute criteria, although there have been a number of criteria described in the literature (2,5,15,19). For most patients, the decision must be individualized, and there are several criteria that should be considered.

The single most useful criterion to predict fracture is the amount of cortical bone destruction. Lesions that fill the medullary cavity but have not destroyed any of the cortical bone are at low risk for fracture. Many destructive lesions destroy bone eccentrically, with damage to a single cortex visible on anteroposterior and lateral radiographs. We try to quantify the amount of bone destruction by studying the two sets of radiographs. If three of the cortices are normal and a single cortex is 50% destroyed, then the amount of bone destruction would be 12.5%. When the amount of cortical bone destruction is assessed at less than 20% to 30%, the risk of fracture is small. When the cortical bone destruction is between 40% and 80%, the risk is much higher. Spontaneous fractures (without trauma) commonly occur in the lower extremity if there is greater than 75% cortical bone destruction (or the equivalent of three missing cortices).

The type of bone metastasis is as important as the amount of bone destruction. Lesions that are purely blastic seldom fracture. In contrast, lesions that are purely lytic are prone to fracture, especially when they are large or in high-stress regions. Lung and renal carcinoma often produce purely lytic metastases, which can progress rapidly. Many patients with prostate carcinoma have purely blastic metastases, which tend to progress slowly. Patients with breast cancer usually have one of three patterns: (a) purely lytic lesions, which are aggressive; (b) purely blastic lesions, which grow very slowly; and (c) a mixed pattern of bone destruction and bone formation.

The location of the metastasis is another factor that must be considered. Very proximal lesions in the metaphysis and epiphysis are less prone to fracture. In contrast, lesions that destroy greater than 50% of the cortical bone in the subtrochanteric, midshaft, or distal third regions of the femur are prone to fracture. In the upper extremity, similar sized lesions in the surgical neck, humeral shaft, and distal third of the humerus may fracture. Fortunately, most pelvic lesions do not fracture unless they become very large or invade the hip joint.

Weight-bearing pain in the lower extremity is another clue to impending fracture. Many patients describe marked pain with ambulation and none when they rest. Place patients on crutches or a walker if they have weight-bearing pain as they await treatment.

Mireles (19) developed a scoring system based on the degree of bone destruction, presence of lytic or blastic metastases, location of the lesion, and type of bone pain. For each of these four variables, there is a score of 0 to 3 for a 12-point grading system. Patients with a score of 5 or greater are prone to fracture, whereas those with a score of 7 or less are less likely to fracture. This system has not been widely accepted because of the overlap between the fracture and nonfracture groups and the subjectivity of the criteria.

We try to individualize the decision for each patient by explaining the risks and benefits of prophylactic fixation. The benefits include (a) an elective procedure that can be optimally timed between courses of chemotherapy, if necessary; (b) usually less blood loss; (c) avoidance of the pain of a pathologic fracture; (d) often a technically easier operation that can usually be performed using closed techniques; and (e) a quicker recovery. The risks are the usual ones for surgery with the potential for an anesthetic complication, bleeding, infection, and a delay in chemotherapy.

The following criteria lead us to recommend prophylactic fixation, particularly if they occur in combination:

1. Cortical bone destruction greater than 40% to 50%
2. Pure lytic metastases
3. Permeative pattern of bone destruction over a length of bone that exceeds two to three shaft diameters
4. Lesions in high-stress areas:
   - Subtrochanteric region of the femur
   - Shaft of the femur
   - Supracondylar region of the femur
   - Surgical neck of the humerus
   - Shaft of the humerus
5. Weight-bearing pain

We employ these criteria without quantifying the factors. Take into consideration the patient's emotional needs, the anticipated loading of the bone, the need for

chemotherapy, and the medical condition of the patient.

NONOPERATIVE TREATMENT

External beam irradiation and protected weight bearing are the mainstays of nonoperative treatment (8). Most patients are treated with a course of either 2,000 cGy in 5 fractions or 3,000 cGy in 10 fractions. In patients who are terminally ill, a single dose of 800 cGy often diminishes their pain. Patients with a solitary lesion and a relatively good prognosis can be treated with a longer course (4,000 to 5,000 cGy in 20 to 25 fractions). Patients with renal carcinoma are frequently treated with a higher dose (4,500 to 5,000 cGy) than those with other carcinomas because of the tendency for disease progression with lower doses.

Have patients with lower-extremity lesions use a walker or crutches during treatment and for 2 to 3 months following treatment. Take serial radiographs at 1-month intervals to judge healing of the lesion. Caution patients with upper-extremity disorders or injuries to avoid heavy loads such as changing a car tire, chopping wood, lifting items greater than 5 to 10 pounds, twisting the cap off a tight jar, carrying heavy suitcases, and so forth.

OPERATIVE TREATMENT

The goal of operative treatment is to achieve immediate rigid fixation so that the patient can bear full weight following the operation. In contrast to the treatment of nonpathologic fracture, in which the surgeon depends on the bone to heal, there may or may not be healing of the fracture in metastatic disease because of the tumor itself or the postoperative radiation or chemotherapy. In patients who live for 5 years following treatment, the failure rates due to disease progression or inadequate fixation can be as high as 40% (9).

Internal fixation devices (intramedullary rods and plates) and prosthetic devices are the most commonly used surgical tools. Methyl methacrylate can be used to supplement the fixation and to fill in defects caused by the tumor (12). If rigid fixation cannot be achieved with an internal fixation device or if the joint surfaces have been destroyed, we prefer to use an endoprosthesis. When we use a prosthetic device we always add an aminoglycoside antibiotic (Tobramycin) to the cement. The risk of infection is higher in patients with metastatic bone disease, so we take the extra precaution.

In contrast to primary bone sarcomas, for which the goal of treatment is to remove the tumor with a wide margin, in metastatic disease, the cancer is controlled with external beam irradiation, hormonal treatment, or chemotherapy. When open surgery is performed, the metastatic tissue is curetted down to the cortex, and methyl methacrylate is usually used to fill the spaces that have been destroyed by the tumor.

Occasionally, metastatic lesions are treated by wide resection (23,24). There are two relative indications for wide resection:

1. A lesion in which there is disease progression despite one or two adequate courses of irradiation. If the patient has a good prognosis, we perform a wide resection to achieve local control and then reconstruct the limb as necessary.
2. In a patient who has renal cell carcinoma and an excellent prognosis, we sometimes perform a wide resection for local control. Many renal cell carcinomas are difficult to control with external beam irradiation alone, especially if the patient survives 3 to 5 years.

Methyl methacrylate is a useful adjunct to fill large defects and to supplement the fixation of internal fixation devices. When large defects are filled, the cement becomes load sharing in compression and helps reduce the deformation of the bone–implant construct. If large voids are left, there will be excessive bending forces on the implant with weight bearing. Metal fatigue failure was common before the use of the cement. The cement is an excellent adjuvant to enhance the fixation of intramedullary rods and screws. When applying the cement, one must be careful to confine the cement to the intramedullary cavity. If the cement leaks into the soft tissue, it can damage neurovascular structures; when large amounts are in the fracture site, the two bones ends will not unite. Most of the healing of pathologic fractures comes from the periosteal tissues.

The cement can be used to increase markedly the fixation of cortical and cancellous screws. The screw can be initially placed and then removed. The cement is injected into the screw hole with a 5-ml syringe, and then the screw is placed and the cement is allowed to harden. An alternative method is to place the cement and then drill and tap it through it. Both methods work well.

PREOPERATIVE EVALUATION AND CONSIDERATIONS

Careful preoperative evaluation of the cancer patient is necessary (9). Make an assessment of the entire skeleton. This can be done by either reviewing a recent technetium bone scan or asking the patient if there is more than one site of bone pain. If you suspect vertebral involvement, study an anteroposterior or lateral view of the cervical spine to make sure that the spine is stable before surgery. When lower extremity surgery is planned, make sure that there are no large lesions in the humeri. Humeral lesions may fracture in the postoperative period while the patient is using a walker or crutches.

Anemia is common in the cancer patient due to multiple factors: marrow replacement by tumor cells, prior irradiation and chemotherapy, and anemia of chronic disease. We generally transfuse patients preoperatively if their hemoglobin levels are below 10 mg/dl. For complex procedures or procedures in which major blood loss is anticipated, we transfuse to a hemoglobin level of 13 mg/dl or higher. Leukopenia is also common. Ascertain if the patient’s white blood cell count is rising or falling if he has received recent chemotherapy. We avoid operating if the absolute white blood cell count is below 500 cells/mm$^3$ at the time of surgery or below that within 2 weeks of surgery. Thrombocytopenia is also common. If the platelet count is below 50,000/mm$^3$, transfuse the patients with 8 units of platelets on the morning of surgery. Depending on the blood loss, platelets may also be needed intraoperatively.

Hypercalcemia is also common in cancer patients (4). Lung and breast carcinomas, lymphoma, and myeloma are the most common malignancies with associated hypercalcemia. Symptoms from hypercalcemia are relative to the serum calcium level and the acuteness of the rise. A rapid slow rise to a higher value may not. Early symptoms of hypercalcemia include anorexia, fatigue, nausea, and vomiting. These symptoms mimic the common cold, so keep a high index of suspicion in the cancer patient. Late symptoms include coma and other neurologic symptoms. Correct hypercalcemia before surgery. Hydration and saline diuresis are the first steps in treatment. Intravenous pamidronate is very effective in lowering the serum calcium level (usually within 24 hours).

In the upper extremity, there can be a wide variety of metastatic lesions. Destructive lesions are more common in the proximal limb girdle—in the scapula, clavicle, and proximal one-half of the humerus. Most lesions of the clavicle, scapula, forearm, wrist, and hand can be treated nonoperatively. Occasionally, a pathologic fracture occurs in the radius and ulna that requires open reduction with a dynamic compression plate with methyl methacrylate augmentation as necessary.

The humerus is the most common bone in the upper extremity to require operative treatment.

Prosthetic Arthroplasty of the Proximal Humerus

There are four indications for prosthetic arthroplasty of the proximal humerus:

1. The humeral articular joint surface has been destroyed.
2. A pathologic fracture of the anatomic neck is present.
3. A large destructive lesion is present so that rigid internal fixation is not feasible.
4. There is progressive disease despite external beam irradiation.

- Perform prosthetic arthroplasty through a deltopectoral approach in a manner similar to arthroplasty for nonpathologic conditions.
- Take the subscapularis off the humerus and address the tumor according to the particular problem.
- If a fracture has occurred through the anatomic neck, resect the proximal fragment with the articular surface and curet the tumor from the distal fragment with straight and angled curets.
- Then prepare the humerus with reamers and broaches and perform a trial reduction.
- Then cement the humeral component into place and test the appropriate head with the humeral endoprosthesis.
- Close the wound in a routine fashion.
Closed Rodding of the Humerus

Closed rodding of the humerus is most frequently used for prophylactic fixation of impending fractures. Usually, at least one cortex (on the anteroposterior and lateral views) is intact. The intact cortices and the intramedullary nail result in a rigid construct, so the patient has use of the upper extremity immediately postoperatively without restriction. Closed rodding can also be used once a fracture has occurred if the amount of bone destruction is small. If there is a large destructive lesion, then it is unlikely that rod fixation alone will result in a rigid construct. In this scenario, we prefer open rodding with methyl methacrylate augmentation.

- Place the patient supine on a radiolucent table with a bump under the affected shoulder. Before prepping the patient, use the image intensifier to ensure visualization of the humeral articular surface and the entire humerus. Some fluoroscopy tables must be turned around 180° to image the upper extremity because they are designed for imaging the lower extremity.
- Prep the limb from the fingers to the angle of the jaw proximally. Include the anterior chest wall to the midline and the posterior shoulder to the vertebral border of the scapula.
- Cover the image intensifier with a sterile drape and maintain sterility throughout the procedure. If the sterile drape is contaminated at some point, change it.
- For closed nailing, make a 5 to 8 cm longitudinal incision from the acromion distally just posterior to the greater tuberosity. Incise the subcutaneous tissue and fascia over the deltoit muscle.
- Divide the deltoit muscle longitudinally with electrocautery down to the rotator cuff.
- Make a 3 cm incision into the rotator cuff about one finger breadth posterior to the greater tuberosity.
- Bring the image intensifier into the field and use a sharp pointed awl to enter the proximal humerus just medial and posterior to the greater tuberosity.
- Use a pointed T-handled reamer to both enlarge the entry point and develop a track in the proximal humerus for the guide wire. Bend the tip of the guide wire at 30° over a 3 cm length to facilitate passage of the guide across the fracture site.
- Then pass the guide wire into the proximal fragment to the level of the fracture site under image guidance.
- Reduce the fracture under the image intensifier and pass the guide wire across the fracture site. Then advance the guide wire as far distally as possible.
- Measure the length of the intramedullary rod by placing a second guide wire of the same length along the intramedullary guide wire and placing the tip at the entry site with the image intensifier.
- Place a Kocher clamp on the measuring guide at the proximal end of the intramedullary guide wire. Use a nail gauge to measure the difference, which represents the length of the guide that is in the intramedullary cavity. An alternate and equally effective method is to use the nail itself as a reference.
- Then sequentially reel the humerus in 0.5 mm increments. The diameter of the nail chosen is the largest nail that will reasonably fit in the intramedullary cavity. We generally choose a nail diameter 1.0 mm less than the last intramedullary reamer.
- Exchange the ball-tipped guide wire for a smooth guide wire, and place the nail over the guide wire into the proximal fragment under image intensification. With the help of the image intensifier, pass the rod across the fracture site. By alternately checking the entry site and the elbow, advance the rod until the proximal end is buried in the humeral head. Then place a proximal interlocking screw.
- If the destructive lesion is small and rigid fixation has been achieved with the rod and proximal locking screw, a distal interlocking is not necessary. When in doubt, add the distal locking screw to the fixation.

Open Rodding of the Humerus

We perform open rodding of the humerus for large destructive lesions and in most pathologic fractures in which we do not believe that we can obtain rigid fixation with closed rodding (Fig. 130.1). The rodding procedure is exactly the same as for closed rodding with the following modifications.

- Use a deltopectoral approach to expose the proximal humerus and an anterolateral approach for lesions of the diaphysis. For large lesions that involve both the proximal and mid humerus, we combine the two approaches.
- Curet the tumor from the medullary canal through a large cortical window in the patients who do not have a fracture and through the fracture site in patients with fractures.
- Then prepare the humerus to accept the intramedullary rod. We rehearse placement of the nail across the fracture site and verify satisfactory reduction and position of the nail before placing the cement in the intramedullary cavity. Be sure that the exposure is adequate and the instruments and nail are ready.
- Withdraw the nail into the proximal fragment proximal to the destructive lesion. We generally remove the guide wire at this point. If the field is very bloody or the exposure is less than adequate, you can leave the guide wire in place; however, that makes it more difficult to inject the cement.
- Mix the cement and inject it with a cement gun using a small nozzle into the distal fragment first and then into the proximal fragment. Hand pressurize the cement to fill all the defects.
- Drive the nail into place and then image the humerus from the shoulder to the elbow to make sure the nail placement is adequate and that there is not excessive cement in the soft tissues.
- Place the proximal locking screws and close the wound in layers with a suction drain.

LOWER EXTREMITY

The pelvis, hip, and femoral shaft are the most common sites of metastatic bone disease (3). Most destructive lesions in the pelvis can be managed with external beam irradiation alone. The most common lesions that require surgery are lesions in the hip and femoral shaft.

Hip

Destructive lesions in the hip can be very disabling. The pattern of disease can be very diffuse with destructive lesions involving the femoral head, neck, or intertrochanteric and subtrochanteric regions alone or in various combinations. In addition, there may be destructive lesions in the shaft of the femur that are separated from the hip lesions by many centimeters. Preoperative planning requires a high-quality plain radiograph of the entire femur. Base the treatment plan on the location of the lesions.

Femoral Neck Lesions

We generally perform bipolar hemiarthroplasty for most femoral neck lesions (3,17,18,21) (Fig. 130.2). The advantage of arthroplasty is that the patient can bear full weight within a month of surgery and pain relief is excellent and reproducible. Occasionally, if the patient has a small femoral neck lesion (less than 40% cortical bone destruction), we perform cancellous screw fixation with three screws followed by external beam irradiation. Most metastatic lesions in the proximal femur are very diffuse, however, and the screw fixation protects only the discrete femoral neck lesions. We often treat patients with femoral neck lesions with external beam irradiation alone and with crutches. Many patients wish to avoid surgery but if the femoral neck fractures, the surgical procedure remains the same—bipolar hemiarthroplasty.

![Figure 130.1. Anteroposterior radiograph of the proximal humerus showing a purely lytic lesion with a pathologic fracture. B: Anteroposterior radiograph following open reduction internal fixation with an intramedullary rod augmented with methyl methacrylate. Note the mature periosteal healing around the cement augmentation.](image-url)
Bipolar arthroplasty can be performed equally well through anterior or posterior approaches. We prefer the Hardinge approach because it provides excellent access to the entire femoral shaft if curettage, wiring, or other procedures are also necessary. It is important to choose a femoral stem that will adequately bypass any lesions in the femoral shaft.

Have available both head and neck replacement prostheses and long-stem prostheses. The head and neck prostheses are very useful if the proximal femoral disease is found to be greater at surgery than what the radiographs showed. Many lesions will progress while the patient waits for surgery. The long-stem prostheses are very useful if an intraoperative fracture occurs. When a long-stem prosthesis is used, it is very important not to pressurize the cement because fat embolization may occur and result in intraoperative cardiac arrest. To prevent this problem, vent the intramedullary canal with a Silastic tube or drill one or two holes in the proximal anterior cortex.

Place the patient in the lateral decubitus position and pad all pressure points.

Using the Hardinge approach, incise the skin and subcutaneous tissues directly down to the fascia and place a Charnley self-retaining retractor to retract the deep fascia.

Excise the trochanteric bursa and release the anterior one third to one half of the gluteus medius and minimus from the proximal femur.

Place the patient in the supine position. Incise the hip capsule with a T-type incision with the horizontal limb parallel to the intertrochanteric line. Place no. 2 Ethibond sutures (Ethicon, Inc., Somerville, NJ) in the capsule to facilitate retraction. Take the vertical limb of the T to the acetabular labrum without cutting the labrum.

Be careful when dislocating the femoral head. If the proximal femur is severely compromised by several destructive lesions and you apply a large amount of force to dislocate the head, the femur may fracture and significantly increase the magnitude of the surgical problems. Three techniques can be used to minimize the risk of fracture (we always employ the first two):

1. Release the capsule anteriorly from the proximal femur around the medial side by flexing and externally rotating the hip while releasing the capsule. This can be accomplished around the medial side and for a short distance posteriorly.
2. Place a bone hook around the femoral neck to facilitate dislocation.
3. Osteolize the femoral neck in situ and remove in a manner similar to that for a patient who has had femoral neck fracture. Be careful not to injure the acetabular cartilage while removing the femoral head.

Once the femoral head has been removed, inspect the articular cartilage visually and by palpation. If there are no defects, then trial the acetabulum for the appropriate diameter femoral head. We also measure the femoral head diameter with a caliper.

Then ream and broach the proximal femur to accept the femoral component. When cementing the component, do not pressurize the cement as for nonpathologic cases.

Close the wound in layers over suction drain.

Before cementing standard or long-stem prostheses, be sure to advise the anesthesiologist so that proper precautions can be taken. These precautions include (a) decreasing the amount of inhalation agent, (b) ensuring that the patient is not hypovolemic, and (c) maximizing the oxygenation of the patient. The femoral canal is not pressurized as is done in nonneoplastic cases.

Intertrochanteric Lesions

- Treat intertrochanteric lesions in a fashion similar to femoral neck lesions.
- Always use the anterior Hardinge exposure.
- Remove the compromised cortex and shape the intertrochanteric region to accept the head and neck prostheses.
- Use straight and angled curets to remove the gross disease. Do not be overly aggressive and thus destroy the remaining cortical shell or there will not be sufficient bone stock to perform the arthroplasty.
- Perform a trial reduction and cement the prosthesis as previously described.

Extensive Proximal Femoral Lesions and Salvage of Failed Internal Fixation Devices

In some patients, it is not feasible to save the proximal femur. In this scenario, we resect the proximal femur and reconstruct the defect with a modular custom prosthesis. There are three common situations in which this procedure is necessary:

1. There is extensive proximal femoral disease and the bone stock is so poor that a standard prosthesis, head and neck prosthesis, or an internal fixation device is not suitable.
2. The patient has undergone one or two courses of external beam irradiation to the hip and has progressive disease. Here, the only way to halt progression is to resect the lesion.
3. The patient has a failed internal fixation device (the metal has fractured, the device has cut out of the bone, or there is disease progression around the implant with loss of fixation).

The positioning of the patient and the surgical approach is exactly the same as for bipolar hemiarthroplasty.

Divide the abductor mechanism longitudinally into two equal anterior and posterior halves. When the anterior half is dissected, release the gluteus medius and minimus from the femur in longitudinal continuity with the vastus lateralis (it is important for postoperative function not to separate them transversely).

Remove the posterior flap from the proximal femur in a similar fashion, although it is much more difficult to maintain the continuity with the vastus lateralis. Also, release the short external rotator muscles.

Release the hip capsule in a fashion similar to that for bipolar arthroplasty, except now release the entire capsule from the femur. Be very careful not to sever the acetabular labrum because it is important for the stability of the prosthesis.

Then osteolize the femur at the desired level and place a Verbrugge clamp on the end of the proximal fragment. The Verbrugge is useful to position the proximal fragment as the soft tissues are released.

By placing the proximal fragment in external rotation, abduction, and internal rotation, release the adductors muscles, psoas tendon and all other soft tissues from the femur. Having released all the soft tissues, release the femoral head from the acetabulum and section the ligament of the head. A hip spud is often helpful to dislocate the head; however, be careful not to injure the acetabular cartilage. Inspect the acetabular cartilage and determine the bipolar head size.

Then assemble the modular trial prosthesis based on the amount of proximal femur removed. If the trial modular components are too long, use a smaller body component.

Once the proper size is found, prepare the femoral shaft with a flexible reamer so that a 1.0 to 1.5 mm cement mantle can be achieved (the stem diameters are 9, 11, and 13 mm; reaming would then be 11 mm for the 9 mm stem, 13 mm for the 11 mm stem and 15 mm for the 13 mm stem).

Then bring the actual prosthesis to be used onto the field and assemble it. Cement the stem into the femur with modern cement technique.

Close the hip capsule carefully with no. 5 Ethibond sutures.

Close the anterior and posterior sleeves of the abductor and vastus lateralis muscles carefully with a combination of no. 5 Ethibond and no. 1 Vicryl sutures (Ethicon, Inc., Somerville, NJ).

Close the remainder of the wound in layers over a suction drain.

Postoperatively, place the patient in a hip abduction brace for 3 to 6 months, allowing full weight bearing immediately following surgery.

---

Figure 130.2. A: Anteroposterior radiograph of the hip with extensive lytic and blastic areas in a woman with breast cancer. There is a minimally displaced femoral neck fracture. B: Anteroposterior radiograph of the hip following reconstruction with a long-stem bipolar endoprosthesis. Note the lytic lesion in the medial cortex of the midshaft of the femur. This lytic area is well bypassed by the femoral stem.
Subcutaneous tissue and the fascia are closed with a single suture, and the skin is closed with staples. No drains are placed. After wound closure, we apply an antiseptic dressing and apply a compression bandage. The patient is then taken to the postanaesthesia recovery area for monitoring. The patient is usually discharged from the hospital on the day of surgery if they have no complications. If the patient has been sedated, they may be discharged on the day of surgery. If they have been under general anaesthetic, they will usually be discharged on the following day, provided they are no longer experiencing pain and have no other complications.

The goals of postoperative care are to (a) halt progression of the bone destruction, (b) avoid postoperative complications, and (c) control pain.

POSTOPERATIVE EXTERNAL BEAM IRRADIATION

External beam irradiation following surgery plays a crucial role in halting disease progression (7,8). Without postoperative irradiation, 20% to 30% of patients will have disease progression with failure of the surgical procedure. In addition, pain control can be achieved only when the tumor cells stop destroying the bone. Began radiation therapy at 2 to 3 weeks following surgery, when the wound has healed. In uncomplicated wounds, we often close the wound with staples. Nylon sutures are used if we anticipate leaving the sutures in place for a prolonged period because most radiation oncologists hesitate to radiate over metal staples because of possible skin reaction. The dose of radiation depends on the clinical situation and the general health of the patient, according to the following guidelines:

1. Patients who are terminally ill and cannot tolerate 2 weeks of daily treatments can be treated with a single treatment 800 cGy in a single fraction.
2. The most common prescription is 2,000 to 3,000 cGy in 5 to 10 fractions; this regimen is excellent for achieving pain control and decreasing the risk of disease progression.
3. For a solitary metastasis in a patient with a good prognosis (survival greater than 12 to 24 months), 4,000 to 4,500 cGy in 20 to 25 fractions is often recommended. In patients with complete fractures, advance the guide wire in the proximal fragment until the fracture site is reached. With image guidance, reduce the fracture and pass the guide wire across the fracture site and advance it to the physeal scar.
4. Plan to ream about 1 to 2 mm larger than the first reamer that obtains good cortical contact.

Destructive Lesions in the Metaphysis

Destructive lesions in the metaphysis of the distal femur and proximal tibia are usually managed by curettage of the lesion, cement augmentation, and plate fixation (Fig. 130.3). It is more difficult to achieve rigid fixation with intramedullary rods when the lesion approaches the articular surface. For the distal femur, we use a dynamic compression screw, whereas in the tibia we use lateral tibia plateau plates or medial buttress plates, depending on the location of the bone destruction. We avoid removing intact cortical bone and generally do the exposure and plate fixation on the side of the greatest bone destruction.

POSTOPERATIVE CARE

The goals of postoperative care are to (a) halt progression of the bone destruction, (b) avoid postoperative complications, and (c) control pain.

POSTOPERATIVE EXTERNAL BEAM IRRADIATION

External beam irradiation following surgery plays a crucial role in halting disease progression (7,8). Without postoperative irradiation, 20% to 30% of patients will have disease progression with failure of the surgical procedure. In addition, pain control can be achieved only when the tumor cells stop destroying the bone. Began radiation therapy at 2 to 3 weeks following surgery, when the wound has healed. In uncomplicated wounds, we often close the wound with staples. 4. Plan to ream about 1 to 2 mm larger than the first reamer that obtains good cortical contact.

Destructive Lesions in the Metaphysis

Destructive lesions in the metaphysis of the distal femur and proximal tibia are usually managed by curettage of the lesion, cement augmentation, and plate fixation (Fig. 130.3). It is more difficult to achieve rigid fixation with intramedullary rods when the lesion approaches the articular surface. For the distal femur, we use a dynamic compression screw, whereas in the tibia, we use lateral tibia plateau plates or medial buttress plates, depending on the location of the bone destruction. We avoid removing intact cortical bone and generally do the exposure and plate fixation on the side of the greatest bone destruction.
POSTOPERATIVE COMPLICATIONS

Complications are common in cancer patients following surgery because many of the patients are immunocompromised, poorly nourished, and prone to deep vein thrombosis and hypercalcemia. The following are some general guidelines to employ:

1. In patients who are immunocompromised, administer intravenous cephalosporin and aminoglycoside for 3 days following surgery. Continue with oral cephalosporin if the wound continues to drain.
2. Provide nutritional supplements to patients who have low albumin levels or lymphocyte counts.
3. Give low-dose warfarin (Coumadin) for 4 to 6 weeks following surgery to patients who have lower extremity surgery. Encourage them to wear their thromboembolic disease (TED) hose for 6 weeks when they are out of bed and ambulating.
4. Check serum calcium levels postoperatively in patients who exhibit any early symptoms of hypercalcemia. Check the serum calcium routinely in patients who have a history of hypercalcemia.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Orthopaedic surgeons tend to think of the skeleton primarily in its mechanical role as the body’s framework, often overlooking its metabolic aspects. Bone is dynamic tissue, and disturbances in its metabolic activity may have significant consequences for the skeleton and the body as a whole. In this chapter, we will explore the implications for orthopaedic surgery of bone metabolism.

CALTROPIC HORMONES

Parathyroid hormone (PTH) is synthesized and released when the body’s serum ionized calcium concentration is low; the net effect of PTH is an increase in serum calcium. PTH causes bone resorption by indirect activation of the osteoclasts (increased number and activity) through osteoblast coupling factors. At high concentrations of PTH, osteoblast activity is inhibited, and at low concentrations, bone formation is stimulated. In the kidney, PTH causes decreased resorption of phosphate in the proximal tubule and increased distal resorption of calcium. PTH also increases renal conversion of 25-hydroxy vitamin D to active 1,25-dihydroxy vitamin D, resulting in increased calcium absorption from the gut (see later).

Vitamin D, a steroid hormone, is also of vital importance in calcium metabolism. It is synthesized from 7-dihydrocholesterol in the skin under the influence of ultraviolet light. As little as 15 minutes a day of direct sunlight exposure on a Caucasian person will produce the daily requirement of vitamin D, but many people, particularly in northern cities, do not meet this requirement during the winter. The cytochrome P450 system forms 25-hydroxy vitamin D, which has a 3-day half-life, from vitamin D in the liver. The kidney then converts this into the active form, 1,25-dihydroxy vitamin D, which has a half-life of 8 hours. This step is under the influence of PTH.

The effect of vitamin D on calcium metabolism is primarily to increase the concentration of calcium. Vitamin D enhances PTH-stimulated bone resorption and promotes increased intestinal absorption of calcium. In the gut, 1,25-dihydroxy vitamin D acts to mature the intestinal villi and to induce the formation of calcium-binding protein by the villi. This binding protein is responsible for active transport of calcium across the gut. In high dietary calcium situations, it is absorbed across the gut by passive diffusion. Vitamin D also promotes the differentiation of cells in the monocyte–macrophage line, which should increase the number of osteoclasts. The possible effect of vitamin D on osteoid mineralization may be mediated through alterations in osteoblasts, enhanced osteocalcin production, or modification of phospholipid metabolism. Vitamin D, however, does not directly stimulate bone formation.

Calcitonin is another peptide hormone active in calcium metabolism. It produces potent and rapid hypocalcemic activity through inhibition of the activity and number of osteoclasts. Calcitonin binds directly to receptors on osteoclasts, resulting in detachment of osteoclasts from the bone and disappearance of the ruffled border. Continued administration of calcitonin produces a gradually smaller response in the osteoclasts. It stimulates bone formation, but this effect wanes as the number of osteoclasts decreases. Calcitonin also acts in the kidney to decrease resorption of calcium from the proximal tubules. It also appears to inhibit production of the active 1,25-dihydroxy vitamin D.

Estrogen has recently been demonstrated to have an effect on calcium metabolism through estrogen receptors on the surface of osteoclasts. Although the mechanisms of estrogen’s effect on bone metabolism have not been clearly identified, accelerated loss of bone following natural, chemical, or surgical oophorectomy is well established. Administration of estrogen with calcium has been shown to slow the accelerated loss of skeletal calcium following menopause.

CALKIN PHOSPHATE METABOLISM

Dietary calcium is absorbed primarily in the duodenum and upper gut; about 15% to 40% of the dietary dose is absorbed, depending on the patient’s age and hormonal status. The body’s requirement for calcium changes with age (Table 131.1). Children need 400–700 mg/day ingested calcium (two or three dairy equivalents daily). During the peak acquisition of skeletal bone mass, between adolescence and age 25, daily intake of about 1,300 mg of calcium (five dairy equivalents) is required. Healthy adults generally require 500 mg/day, pregnant women 1,500 mg/day, and lactating women 2,000 mg/day. Postmenopausal women generally require 1,500 mg/day, as do patients who have had a major fracture.

Table 131.1. Daily Calcium Requirements

Calcium absorption is facilitated by the appropriate gastric pH, adequate 1,25-dihydroxy vitamin D, and a calcium-to-phosphate ratio of 1:1 or 1:2. Achlorhydria; decreased vitamin D; increased phosphates; increased fat, phytates, or oxylates in the diet; sprue; blind-loop disorders; and renal disorders can decrease the
Phosphate is absorbed primarily in the lower bowel and excreted in the urine. The daily requirement is about 1,000–1,500 mg and is rarely a limiting factor in American diets. Aluminum and beryllium can decrease the absorption of phosphate; PTH increases its excretion.

**PAGET’S DISEASE**

Paget's disease is a disorder characterized by a disturbance in the rate of bone turnover, initiated by an early increase in bone resorption by osteoclasts and followed by excessive and pathologic bone formation by osteoblasts. The result is distorted bones with thickened cortices, coarse trabeculations, and an immature woven appearance. Paget's disease can affect any bone but most commonly afflicts the femur, spine, pelvis, and cranium. Paget's disease may be monostotic or polyostotic, and it may or may not be symptomatic.

The etiology of Paget's disease remains unknown. There appears to be a familial clustering, with a positive family history in 14% to 30% of patients with Paget's disease. A correlation of Paget's disease and certain human leukocyte antigen (HLA) patterns has been noted (83). In addition, a viral etiology for Paget's disease has been proposed (64,65,78). Inclusions resembling viral nuclear capsules have been described in osteoclasts in pagetic bone; these are not seen in osteoclasts or osteoblasts in normal sites in the same patient. These viruslike particles resemble paramyxovirus or measles virus (65). Viral etiology has not been definitively proved, but it is possible that a susceptible host may contract a slow type of virus, predisposing the host to Paget's disease later in life.

Paget's disease afflicts men more commonly than women by a 3:2 ratio, and it is seen most often in patients over age 50. It is estimated that 3% to 4% of people over age 45 and as many as 8% of those over age 80 in the United States may have Paget's disease, a total of more than 3 million people (83). This disease is most common in Europe, North America, Australia, and New Zealand, and it appears more common in people of northern European ancestry than of southern European ancestry, although Scandinavians have a particularly low rate. The disease is uncommon in Asians and blacks, although most clinical series in North America have black patients.

**DIAGNOSIS**

Perhaps 10% to 20% of patients with Paget's disease are asymptomatic when diagnosed incidentally through radiology or laboratory work (e.g., by an elevated alkaline phosphatase). In symptomatic Paget's disease, patients experience bone pain either with rest or with motion. Pagetic bone also has increased vascularity, leading to a warmth of the bone or of the skin over the bone. Back pain is common in patients with Paget's disease, secondary to spinal stenosis or vertebral compression fractures. Paraplegia can occur acutely, often in association with a giant-cell tumor secondary to Paget's. Paget's disease may cause an increase in the size of the skull, with or without frontal bossing. Hearing loss may also occur.

Radiographically, pagetic bone may have small transverse lucencies or pseudofractures, typically on the convex surfaces of the weight-bearing long bones. Bowing of the femur or tibia may also occur, either with or without pseudofracture. Typical radiologic appearance includes areas of focal bone resorption and formation and a disordered trabecular pattern (Fig. 131.1, Fig. 131.2). Bone size is expanded and the cortices are thickened. A flame-shaped osteolytic wedge may be seen, as may bony deformities, incomplete pseudofractures, and frank pathologic fractures.

![Figure 131.1. Paget's disease. Notice coarse trabeculation.](image1)

![Figure 131.2. Paget's disease. Notice enlargement of bone and coarse trabeculation.](image2)

Classically, in Paget's disease, involvement at one end of the bone progresses toward the other end. A bone scan is more useful than a skeletal survey to discover the extent of the disease. A gallium scan will differentiate tumor from Paget's disease (only tumor is positive). Elevated serum alkaline phosphatase and bone collagen products (N-telopeptide, pyridinoline) are typical findings. The alkaline phosphatase level is more useful as a screening tool. Either alkaline phosphatase or collagen breakdown products may also be used to monitor response to treatment, with a 50% reduction considered to be a good clinical response.

Histologic examination of pagetic bone shows marked abnormalities. There is an increase in the cellular activity of both osteoclasts and osteoblasts, with fibrosis and fibrovascular invasion of the marrow. The osteoclasts seen in Paget's disease have extremely numerous nuclei with very large nucleoli (Fig. 131.3). Active Paget's disease as just described presents a classic histologic appearance. "Burned-out" sclerotic pagetic bone, however, is more difficult to diagnose definitively because the bone reverts to near normal, although a mosaic-type bone pattern can be seen microscopically with polarized light.
The prognosis for patients with Paget's disease and osteogenic sarcoma is poor despite radical surgery and chemotherapy (although fibrosarcoma and chondrosarcoma may be seen as well. Arolina, Italy. They contain viral particles and are exquisitely sensitive to corticosteroid therapy (In symptomatic patients with Paget's disease, the incidence of tumors is about 2% to 4%; however, when all patients who have Paget's disease of any variety are

PAGET'S SARCOMA

the disease. Even after successful union, protective bracing may be needed for 3–6 months to allow for remodeling, which is slow.

With these exceptions, fractures in Paget's disease tend to heal with abundant callus. Delayed union or nonunion is more common in the sclerotic burned-out phase of the disease. Even after successful union, protective bracing may be needed for 3–6 months to allow for remodeling, which is slow.

ORTHOPAEDIC IMPLICATIONS

Fractures, particularly pathologic fractures, are the most common complication in Paget's disease. An estimated 10% of patients with extensive Paget's disease will suffer pathologic fracture, usually of the femur, tibia, or forearm (62). Nonunions are common, particularly with femoral neck and subtrochanteric fractures (5,15,24,69).

Fractures occurring through secondary sarcomas account for 5% to 20% of fractures in pagetic bone (70). Pseudofractures in Paget's disease occur most commonly in the tibia and the proximal femur, typically on the convex side of the bone, although they may be seen on the medial concavity of the femur as well. Treatment includes bracing and protected weight bearing in addition to pharmacologic treatment until the patient becomes pain free. Radiologic healing often lags behind clinical healing.

Figure 131.4. Corrective osteotomy with intramedullary fixation. A: Preoperative. B: Postoperative.

ORTHOPAEDIC IMPLICATIONS

Fractures, particularly pathologic fractures, are the most common complication in Paget's disease. An estimated 10% of patients with extensive Paget's disease will suffer pathologic fracture, usually of the femur, tibia, or forearm (62). Nonunions are common, particularly with femoral neck and subtrochanteric fractures (5,15,24,69).

Fractures occurring through secondary sarcomas account for 5% to 20% of fractures in pagetic bone (70). Pseudofractures in Paget's disease occur most commonly in the tibia and the proximal femur, typically on the convex side of the bone, although they may be seen on the medial concavity of the femur as well. Treatment includes bracing and protected weight bearing in addition to pharmacologic treatment until the patient becomes pain free. Radiologic healing often lags behind clinical healing.

Actual fractures in Paget's disease are often short, oblique, or transverse. If they fail closed management, they are best treated by an intramedullary device. Passage of an intramedullary device may be technically difficult because of the disordered architecture of the pagetic bone.

Femoral neck fractures are a particular problem and often do not heal in patients with Paget's disease; the reported rate of nonunion is 75% to 90% (62). If these fractures are displaced, perform prosthetic replacement. Inter trochanteric fractures, on the other hand, usually unite after fixation with a sliding screw-plate device.

Subtrochanteric fractures are particularly difficult to handle in patients with Paget's disease. Intramedullary fixation is preferable from a biomechanical standpoint but may be difficult because of excessively soft or sclerotic bone and because of bony deformity of the femur. Sometimes a corrective osteotomy in addition to intramedullary fixation may be required (Fig. 131.4). Femoral shaft fractures are typically managed in a similar way, but tibial fractures can often be managed by closed means because of the transverse configuration of the fracture. Surgical treatment of a fracture, however, may provide an opportunity to correct a deformity.

The main agents used for the treatment of Paget's disease in the United States are calcitonin, bisphosphonates such as etidronate, and occasionally mithramycin. Calcitonin is available as salmon or human calcitonin; the salmon calcitonin is more potent by weight. Calcitonin is a peptide and is currently given by an intranasal spray. In patients with painful pseudo fracture or frank fractures, calcitonin is given initially at 200 units/day until there is evidence of decreased bone pain or fracture healing, and the alkaline phosphatase level falls. The dose can then be decreased to three times a week to maintain the alkaline phosphatase at a lower level. Side effects of nasal calcitonin include dry nares (2%).

With these exceptions, fractures in Paget's disease tend to heal with abundant callus. Delayed union or nonunion is more common in the sclerotic burned-out phase of the disease. Even after successful union, protective bracing may be needed for 3–6 months to allow for remodeling, which is slow.

PAGET'S SARCOMA

In symptomatic patients with Paget's disease, the incidence of tumors is about 2% to 4%; however, when all patients who have Paget's disease of any variety are included, the incidence is usually about 0.1% (82). The most commonly seen benign tumors are giant-cell tumors, which are common in patients with an ancestry from Arolina, Italy. They contain viral particles and are exquisitely sensitive to corticosteroid therapy (84). The most common malignant tumors are osteogenic sarcomas, although fibrosarcoma and chordrosarcoma may be seen as well.

The prognosis for patients with Paget's disease and osteogenic sarcoma is poor despite radical surgery and chemotherapy (34). At Memorial Sloan-Kettering Cancer
Center, there have been no survivors for axial tumors, but 23% of appendicular tumors have a 5-year survival. Any patient with Paget's disease who develops new pain in a previously pain-free area of Paget's disease, or a lytic area in sclerotic Paget's bone, must be evaluated for a possible tumor.

ELECTIVE ORTHOPAEDIC SURGERY

Patients with Paget's disease not only have bone pain but may also have arthritis associated with either biomechanical factors or pagetic involvement of the joints. For patients with severe disabling arthritis of the hip, total joint replacement may be considered, but several technical considerations should be noted. There is often significant varus deformity of the proximal femur, and the medullary canal may be distorted. The bone may also be extremely sclerotic, making reaming difficult.

In patients with active Paget's disease, increased blood loss may be expected, and postoperatively the patients have a higher incidence of heterotopic ossification. On the acetabular side, about 25% of patients may have a protrusio acetabuli (27). Because many patients with Paget's disease also have involvement of the lumbar spine, it is extremely important to carefully separate possible lumbar spine pain from hip pain before undertaking arthroplasty of the hip. Local instillation of anesthesia into the hip may help determine the primary cause of pain.

Long-term follow-up of cemented total hip replacement in patients with Paget's disease shows a slightly increased incidence of revision for aseptic loosening, but otherwise good or excellent results (55-58,61). These studies reviewed cemented total hip arthroplasty; there have been no long-term studies of porous ingrowth implants in patients with Paget's disease. Because of the modeling and remodeling disorders in Paget's, uncemented total hip replacement is not recommended. Treat patients undergoing total joint arthroplasty with calcitonin, 50 units three times a week, beginning 1 month preoperatively and continuing for about 5–6 months postoperatively, so as to decrease perioperative bleeding and postoperative hypercalcemia.

Total knee replacement has also been reported in patients with Paget's disease, with up to a 12-year follow-up. No unusual technical difficulties were encountered (7,9).

The other type of orthopaedic surgery that may be required in Paget's disease is osteotomy to correct malalignment in the leg. Osteotomy, particularly of the femur and tibial shaft, is indicated for symptomatic and recurrent or recalcitrant pseudofractures. Surgery is usually performed with an interlocking intramedullary rod after one or more closing-wedge osteotomies. If the intramedullary canal is obstructed, double plating with bone grafting can be used.

RICKETS AND OSTEOMALACIA

Rickets and osteomalacia are respectively the childhood and adult consequences of a failure to mineralize either physeal cartilage (children) or osteoid (adults) due to disorders in vitamin D metabolism.

The classic clinical description of a child with rickets is of an apathetic, irritable child who is shorter than usual and has a positive Gower's sign, frontal bossing, and an enlarged epiphysis. He also may have a rachitic rosary or Harrison's groove. The radiologic findings in rickets include a wide epiphyseal plate with cupping, and an indistinct zone of provisional calcification (Fig. 131.5). Long-bone bowing, genu valgum or genu varum, and stress fractures (Looser's lines) are also seen (Fig. 131.6).

The adult patient with osteomalacia may have localized bone pain and muscle weakness. Radiologic findings may be identical to those seen in osteoporosis, except that Looser's lines appear in patients with osteomalacia. Other radiologic findings, such as “rugger jersey spine,” have also been described in patients with osteomalacia.

Laboratory findings in rickets and osteomalacia may vary, depending on the etiology of the problem. Phosphorus is decreased, alkaline phosphatase is increased, and 25-hydroxy vitamin D is decreased in patients who have a vitamin D deficiency syndrome (Table 131.3). Vitamin D deficiency may be secondary to decreased exposure to ultraviolet light or to a vitamin D deficiency in the diet. Although milk and dairy products in the United States are typically fortified with vitamin D, certain people are at risk because of their dietary habits. A significant number of American blacks are lactose intolerant and therefore avoid dairy products. Strict vegetarians who do not eat any dairy products are at risk for rickets or osteomalacia.

Table 131.3. Disorders of Mineral Metabolism
Treatment depends on the etiology. Vitamin D deficiency is typically treated with 50,000 units of vitamin D plus calcium. Vitamin D–resistant rickets (a proximal tubular defect in excretion of phosphorus) requires increased phosphate in the diet plus 1,25-dihydroxy vitamin D in low doses.

Rickets and osteomalacia are typically very responsive to treatment once the diagnosis is made. Patients may consult an orthopaedic surgeon because of bone pain or bony deformity. Specific orthopaedic intervention is rarely necessary, but bracing of the extremities or spine may be required, particularly in children. In addition, a patient with significant bony deformity may need an osteotomy. With appropriate pharmacologic treatment, such a patient can produce appropriate amounts of osteoid, and the osteotomy should heal well.

**RENA L OSTEODYSTROPHY**

Renal osteodystrophy encompasses a continuum of diseases, ranging from a low-turnover bone disease resembling osteomalacia to a high-turnover disease resembling secondary hyperparathyroidism. In renal disease, the physiologic PTH–vitamin D axis is altered. Phosphat e retention and hyperphosphatemia occur as a result of impaired renal phosphorus clearance. Hypocalcemia occurs, partly as a result of increased calcium excretion. In addition, hydroxylation to form 1,25-dihydroxy vitamin D is diminished, which in turn impairs calcium absorption across the gut. The effect of PTH on the kidney is also diminished.

In patients with the high-turnover form of the disease, hyperphosphatemia is an important factor in the development of the secondary hyperparathyroidism. There is abundant histologic evidence of active bone resorption, including increased number and size of osteoclasts, increased percentage of bone surface covered with osteoclasts, and increased number of Howship's lacunae. Patients may develop ost etitis fibrosa, in which fibrous tissue accumulates in the bone. Osteoblast activity also increases in patients with ost etitis fibrosa (59,62). Moderate increases in the amount of ost etid may be seen, and the ost etid often appears woven because of the increased bone turnover. Clinically, bone pain, brown tumors, and ulcers may be seen. On radiographs, the classic salt-and-pepper skull, soft-tissue calcifications, osteopenia next to osteosclerosis, and erosions of the phalaneg al tuft and distal clavicle may be seen. These changes parallel those seen in patients with primary hyperparathyroidism.

In children, metaphyseal changes and epiphyseal plate changes are common and have been described as rickets-like. Unlike patients with congenital rickets, patients with renal osteodystrophy prematurely develop genu valgum deformities. In addition, slipped capital femoral epiphysis (SCFE) is a common complication of the disease in children (59). Epiphyseal slippage may also occur in the lower femoral epiphysis or the distal tibial epiphysis.

The opposite extreme of renal osteodystrophy may be seen as a low-turnover bone disease similar to osteomalacia and aplastic bone disease. Initially thought to be the result of vitamin D deficiency, it is now clear that aluminum toxicity can account for osteomalacia seen with renal osteodystrophy (Fig. 131.7). Aluminum contamination of water used in dialysis solutions has been identified as a source; a decrease in the aluminum in the filtrate reduces the prevalence of the osteomalacia (53,71–74).

**Figure 131.7.** A: Photomicrograph shows extensive hyperosteoideiosis with smudged mineralization front (Von Kossa, ×80). B: Photomicrograph shows aluminum deposition at the mineralization front. Patient has renal osteodystrophy (aurin tricarboxylic acid stain, ×80).

In addition, patients with renal osteodystrophy use aluminum-containing phosphate binders to prevent hyperphosphatemia and secondary hyperparathyroidism. These buffers can substantially increase the aluminum load in the body. Aluminum is known to deposit along the mineralization front, which may impair the calcification of the osteoid (22–56). Aluminum is also associated with a substantial decrease in the number of osteoblasts. Histologically, patients who have a low-turnover type of bone disease have bone characterized by excessive ost etid or unmineralized collagen. The ost etid seams are widened and often multilamellar in appearance, with more of the bone surface covered by osteid. Osteoblastic activity is markedly reduced. Aluminum can be demonstrated in these areas by staining. The use of calcium carbonate to buffer high phosphate has largely prevented this disorder.

Patients rarely display one extreme or the other of renal osteodystrophy. Typically they have some type of mixed pattern characterized by secondary hyperparathyroidism as well as evidence of osteomalacia. The most common clinical manifestations of renal osteodystrophy are bone pain, muscle weakness, skeletal deformities, ectopic calcification, and growth retardation in children.

Bone pain is common in renal osteodystrophy and is usually aggravated by weight bearing. It is most common in the lower back, hips, and legs, although heel and ankle pain may also be noted. Bone pain is more common in patients with aluminum-related bone disease than in those with ost etis fibrosa (63). Muscle weakness, often of a proximal myopathy type, may also be noted with severe renal disease. In some cases, a favorable clinical response has been seen after treatment with 1,25-dihydroxy vitamin D3 and with deferoxamine chelators for treatment of aluminum-related bone disease (12–69).

Skeletal deformities are a major clinical feature of renal osteodystrophy. They are more common in children and may affect either the axial or the appendicular skeleton. In adults, particularly those with aluminum toxicity, deformities are predominantly confined to the axial skeleton.

In children up to age 4, abnormalities seen in renal osteodystrophy resemble those of vitamin D–deficiency rickets. In children between ages 4 and 10, deformities of the long bones, particularly bowing of the tibia and femur, are common; genu valgum is particularly common. SCFE is common in pediatric patients, particularly those with secondary hyperparathyroidism. Despite vitamin D treatment, 20% to 25% of pediatric patients treated with long-term dialysis require orthopaedic intervention to correct bony deformities (23).

Patients with renal disease also often have ectopic calcification, often in a periarticular location. These calcifications are most common when the calcium–phosphorus ion products exceed 75 (62). Ectopic calcifications are more common in adults but can also occur in children with severe end-stage disease. Another complication of long-term renal disease is amyloidosis. The most common presenting syndrome is carpal tunnel syndrome, but pathologic fracture or scapulothoracic parainarthritis may also be present (23,44). Arthritis may involve the metacarpophalangeal and interphalangeal joints, hand, shoulder, wrist, and knees. Bone cysts may be found in the femoral head, acetabulum, humerus, radius, carpal bones, tibial plateau, and pubis; these may resemble brown tumors (44). Distinctive changes may occur in the bone with sites of amyloid deposition, and fractures can occur through such cysts. There is no clear treatment for this problem.

Primary initial treatment of renal osteodystrophy is medical and dietary. Restrict phosphorus intake in the diet to 400–800 mg/day. Phosphorus-binding antacids may be required to decrease the absorption of phosphorus. Calcium supplements are useful; calcium carbonate not only increases the amount of calcium available for absorption but also acts as a phosphate-binding agent. Do not, however, give calcium supplements until the serum phosphorus levels are reduced to about 6.5 mg/dl or less or until the calcium–phosphorus ion product is below 75, to minimize the risk of extraskelatal calcification (63). If calcium carbonate is to be used to bind phosphate, it should be taken with a meal to increase its phosphate-binding efficiency.

Vitamin D derivatives and 1,25-dihydroxy vitamin D have also been used in the treatment of renal osteodystrophy. Oral calcitriol (0.25 to 1.5 µg/day) in patients with renal osteodystrophy has improved muscle strength, decreased bone pain, and increased growth in uremic children (12). The major side effect of this treatment is hypercalcemia. Hypercalcemia developing within the first few weeks of treatment may indicate either a limited amount of bone disease or autonomous
If secondary hyperparathyroidism is a prominent manifestation of the renal disease, parathyroid surgery can be considered, especially if patients have persistent hypercalcemia, intractable pruritus, progressive ectopic calcifications, severe skeletal pain, or fractures.

The management of aluminum toxicity in renal disease is difficult. The chelator deferoxamine substantially increases the removal of aluminum with both hemodialysis and peritoneal dialysis, which may improve symptoms and bone histology (28,29,83). Currently, it is recommended that deferoxamine be given only to patients with symptomatic aluminum toxicity. The dose should not exceed 1–2 g/week; measure aluminum levels and plasma regularly.

Several orthopaedic complications in renal bone disease have already been mentioned. In children, SCFE and deformities of the long bones are most prominent. SCFE requires pinning and appropriate medical treatment. Bowing of the extremities can sometimes be treated with bracing but often require osteotomy. In both adults and children, bone pain may be due to pseudofractures seen as Looser’s lines, and these may progress to frank fractures. The treatment of bone pain associated with pseudofractures should be medical management combined with decreased weight bearing until the pain has resolved. An actual fracture should be treated as any other fracture, with the expectation that healing will be delayed.

Carpal tunnel syndrome resulting from amyloid deposition is unlikely to be successfully managed by conservative treatment alone, and surgery may be required. There are no good long-term studies available for total joint replacement in patients with renal osteodystrophy, but because of the severe derangement of bone metabolism, uncemented arthroplasty cannot be recommended. Dialysis patients have a high rate of prosthesis loosening, but patients who have undergone transplantation do well.

If you are contemplating surgery on a patient with renal osteodystrophy, do an extensive medical workup first. Patients with severe renal disease may have clotting abnormalities and often have severe anemia. They also have arteriovenous fistulae from dialysis, which require careful management in the hospital. Infections can be particularly severe in patients with renal osteodystrophy; make every effort to minimize any chance of contamination. Overall, the patient's medical condition must guide any decisions about elective orthopaedic surgery, and in emergency situations optimize the patient’s medical status before doing any surgery.

### OSTEOPOROSIS

Osteoporosis has been defined by the National Institutes of Health (NIH) Consensus Conference as an age-related disorder characterized by decreased bone mass and increased fracture risk in the absence of other recognizable causes of bone loss (69). The fractures most commonly seen in osteoporosis involve the vertebral body, proximal femur, wrist, humerus, pelvis, and ankle and foot.

Osteoporosis is a major public health problem in the United States, where it is estimated that more than 20 million people have it. As the population ages, this number will increase dramatically. More than 1.2 million fractures a year are attributed to osteoporosis, including about $35,000 vertebral fractures, 172,000 wrist fractures, and 200,000 hip fractures (38). The financial cost of osteoporosis in 1982 was over $6 billion annually (60).

Risk factors for osteoporosis include having low body weight, and being postmenopausal, white, and of northwestern European descent (77). Other factors include poor calcium intake, a sedentary lifestyle alcohol and use, and, most prominently, any history of premature menopause or amenorrhea. Factors that increase risk for hip fracture besides osteoporosis include falls, lack of weight gain since age 25, greater height, poorer self-rated health status. History of hyperparathyroidism, use of oral or injectable glucocorticoids, and genetic factors, such as small bone size and family history of fractures, also increase risk.

The type I pattern is most common in recently postmenopausal women, predominantly age 51 to 65. It involves rapid bone loss primarily from areas of trabecular bone after natural or surgical menopause and can result in the loss of 2% to 3% of bone mass per year (8% per year trabecular and 0.5% per year cortical). From 6 to 10 years after menopause, the rate returns to the slow phase (51,52,57,72,74,75).

</tbody>
</table>

Two types of osteoporosis correlate well with the timing and patterns of the various fracture syndromes seen in osteoporosis. The incidence of vertebral fractures and Colles' fractures rises soon after menopause, as these areas derive much of their mechanical strength from trabecular bone (73). The incidence of hip fractures, in which cortical bone loss is more important, increases slowly with age until late in life. One third of women who live to age 90 suffer a hip fracture (69).

The radiologic findings in osteoporosis include osteopenia, seen when more than 30% of mineral is absent; loss of horizontal trabeculae of the vertebral bodies; wedge fractures to the thoracic spine; end-plate fractures or crush fractures of the lumbar spine; stress fractures of the pelvis; and fractures of the humerus, wrist, hip, supracondylar femur, and tibial plateau. In pure osteoporosis, laboratory studies are normal except for a slight increase in alkaline phosphatase after new fractures. Although osteoporosis is the number one cause for fractures in these locations, other possible metabolic abnormalities must be ruled out before making the diagnosis of osteoporosis.

Hormone excess can lead to osteoporosis. Hyperparathyroidism is a relatively common cause of osteopenia, and patients with the condition typically have an increased PTH level, hypercalcemia, and hypophosphatemia. Most of the patients are identified by incidental laboratory findings.

Hypothyroid patients may also be osteopenic. The T3 and T4 values may be elevated or may be within the high-normal limits. Iatrogenic hyperthyroidism is common in women who are slightly obese and have been placed on thyroid medication. The key diagnostic tests for patients with suspected hyperthyroidism is the thyroid stimulating hormone–radioimmunometric assay (TSH-IRMA). Other endocrinopathies associated with osteoporosis are unstable diabetes and Cushing's disease. Over 99% of cases of Cushing's disease leading to osteoporosis are iatrogenic, with patients on doses of prednisone exceeding 7.5 mg/day. Diabetes can cause...
osteoporosis by hypercalcioria and negative nitrogen balance.

Neoplastic disorders can also account for osteopenia and should be sought in patients with localized vertebral fractures. Two percent of osteopenic patients have bone-marrow abnormalities; 50% of these are multiple myeloma. Typical laboratory findings for these patients are decreased hemoglobin, increased sedimentation rate, and abnormal serum or urinary protein electrophoresis. In about 15% of patients with multiple myeloma, the serum electrophoresis may be normal. Osteopenic patients with abnormal blood parameters may require a bone-marrow biopsy. Once endocrinopathy and bone-marrow pathologies have been eliminated as causes for osteopenia, the differential diagnosis is between osteomalacia and osteoporosis.

About 8% of our patients with osteopenia display various degrees of osteomalacia. About half of these patients have abnormal blood studies—notably decreased urinary calcium, decreased to low-normal serum calcium, decreased 25-hydroxy vitamin D, low phosphorus, and elevated alkaline phosphatase. The remaining patients with osteomalacia can be differentiated from those with true osteoporosis only by evaluating a transiliac bone biopsy.

A double tetracycline labeling program provides the maximum information. Patients whose biopsies demonstrate more than 5% osteoid volume are considered to have osteomalacia, and the source should be sought. The bone biopsy can also help distinguish between high-turnover and low-turnover forms of osteoporosis. With the biopsy demonstrating less than 5% osteoid volume and less than 0.5% of the trabecular surface with active resorption, the patient is classified as having quiescent or low-turnover osteoporosis; this accounts for about two thirds of the patients with osteoporosis. Patients with more than 0.5% active resorption on the trabecular surface and less than 5% osteoid volume are classified as having high-turnover osteoporosis.

Treatment differs for these two types of osteoporosis. Treatments for the other forms—osteopenia and osteomalacia—should be individualized to the underlying etiology (Table 131.5).

Table 131.5. Workup of Osteoporosis

Once the diagnosis of osteoporosis is clinically made, quantification of bone mass is necessary for confirmation of the diagnosis and longitudinal follow-up. Plain radiographs are of little use in measuring a patient's bone mass. A decrease or loss of the horizontal trabecular pattern on spinal radiograph suggests osteopenia; such a finding is, however, somewhat technique dependent, and up to 40% of spinal bone mass can be lost before this finding is noted. Dual-energy x-ray absorption uses an x-ray source that emits two different energies, allowing the soft-tissue component to be subtracted. This technique permits assessment of fracture risk of the vertebral bodies and the femoral neck. The radiation dose is low (about 5–15 mrad), and the precision is 1% to 2% for the vertebral body and 2% to 4% for the femoral neck (43). Compression fractures, scoliosis, and soft-tissue calcifications may distort the data.

Total body bone mass or local bone mass determinations can also be made. New studies using this method in a lateral position appear to improve its sensitivity by 50% (85) (Table 131.6).

Table 131.6. World Health Organization Diagnostic Criteria for Osteoporosis

Quantitative computed tomography (CT) scanning permits the measurement of spinal trabecular bone density and is very sensitive to change; its precision is 3% to 15% (43). There is about 20 times as much radiation involved as in dual-energy x-ray absorptiometry; The CT scan may be affected by artifacts caused by marrow fat or vertebral veins.

Both dual-energy x-ray absorptiometry and quantitative CT scanning are used to identify patients with low initial bone mass, or to monitor patients longitudinally to evaluate decreasing bone mass. Other methods to identify osteoporotic patients include radiographic wedge, single-beam absorptiometry, and ultrasound. Although these measures can be used to identify a population at risk for fracture (those with spinal density below 1 g/cm²), they have proved to be of little value in predicting whether a particular patient will suffer a fracture during a specific period of time.

PREVENTION

The most effective way to deal with osteoporosis is to prevent it (Table 131.1), but uniform preventative measures have not been widely adopted. Clearly, patients who develop a high peak bone mass by age 25, maintain adequate calcium intake, and perform weight-bearing exercises will have a decreased risk of developing symptomatic osteoporosis. During the period of maximum bone accretion (age 13 to 25), we recommend a dietary regimen of about 1,200 mg/day elemental calcium with 400 units vitamin D, as well as an impact-type exercise program.

Teenagers, particularly girls, often do not eat enough protein, carbohydrates, and calcium. Girls who develop amenorrhea or oligomenorrhea at an early age are at particular risk for developing osteoporosis later, because they never attain sufficient peak bone mass. These patients can actually develop a negative calcium balance and lose bone mass while young. Although some have suggested that exercise causes both amenorrhea and bone loss, it has been shown that girls who maintain normal menstrual cycles while exercising are at no increased risk for osteoporosis. Young athletes who do develop amenorrhea or oligomenorrhea should be considered for cyclic estrogen/progesterone or birth-control pills in an effort to reestablish normal menstrual cycles.

Premenopausal women age 25 and older (and men of similar age) should be maintained on a calcium intake of about 800 to 1,000 mg/day with 400 units of vitamin D, as well as a reasonable exercise program.

TREATMENT

Table 131.7 summarizes the many possible treatments once the diagnosis of osteoporosis is established. Recommend behavior modification, such as the cessation of smoking and decreasing alcohol intake, for all patients, but do not expect a high level of compliance. Another nonpharmacologic intervention is to increase the level of
exercise. It is well known that immobilization leads to increasing bone resorption (67). Prospective studies have shown that 1 hour of exercise two or three times a week is effective in increasing lumbar spine density and total body calcium in postmenopausal women compared with sedentary control groups (14,47). Spinal extension, abdominal muscle strengthening, and impact-loading exercises such as walking, square dancing, or weight lifting may be very beneficial for patients with osteoporosis.

Table 131.7. Updated Protocol for Treatment of Osteoporosis at the Hospital for Special Surgery

**Calcium**

Although a dietary calcium deficiency is known to adversely affect the skeleton, the role of calcium supplementation in preserving or augmenting skeletal mass is unclear. Menopausal status may determine whether calcium therapy will be effective in osteoporotic patients.

At a study at the Hospital for Special Surgery, osteoporotic women were put on 1.5 g/day calcium, 800 units/day vitamin D, and an exercise program. The patients were divided into three age groups: premenopausal, early postmenopausal (within 10 years of menopause), and late postmenopausal (65 years or older). Serial dual-photon absorptionmetry measurements were obtained from the lumbar spine and femoral neck. Calcium therapy (with exercise and vitamin D) resulted in a significant 3% to 5% increase in bone mass of the femoral neck among all three groups tested in the first and second year of therapy.

In the spine, premenopausal women showed no change in density instead of the expected 0.3% to 0.5% decrease per year. Late postmenopausal women showed a slight increase in bone density. Early postmenopausal patients, however, lost vertebral bone density at the rate of 2.2% per year, the rate of loss reported elsewhere (18,75).

This study suggests that although calcium supplementation was beneficial in the younger and oldest patients, calcium supplementation alone will not reverse or significantly slow the rate of acute postmenopausal bone loss. Women with calcium intake below 400 mg/day, however, can be significantly aided by calcium. We currently recommend that all women over age 35 take 1,200 mg/day of calcium; postmenopausal women should take 1,500 mg/day. Give vitamin D, 400–800 units/day, to all patients.

**Estrogen**

Estrogen replacement therapy (ERT) has also been effectively used in the treatment of osteoporosis (16,48). Many studies demonstrate that low-dose estrogen therapy, particularly when begun shortly after menopause, can arrest or decrease spinal bone loss, and decrease by 50% the incidence of radial, vertebral, and proximal femoral fractures (18,32,33,42,41,52). Postmenopausal patients with a strong family history of osteoporosis, those with a bone mass more than 1.5 standard deviations below the mean, or those who demonstrate a loss of 4% or more of bone per year on serial bone-density measurements are strong candidates for estrogen therapy or other antiresorptive programs.

Although there is an increased risk of endometrial cancer in women taking only exogenous estrogens, low-dose estrogens combined with progesterone actually lower the incidence of endometrial cancer (19). Of somewhat greater concern is the possibility of an increased risk of breast cancer in patients on estrogen. Several studies of combined treatment with low-dose estrogen and progesterone indicate that the risk of breast cancer may not be appreciably increased (19,38,91). The general consensus, however, is that estrogen, even in combination, may marginally increase breast-cancer risk. Unopposed estrogen therapy appears to have a beneficial effect on atherosclerotic heart disease and mental function (20).

Patients in whom estrogen therapy is absolutely contraindicated include those with preexisting breast cancer, regardless of receptor status, and patients with a history of thromboembolic disease on hormonal therapy (95). Excess uterine bleeding, hypertriglyceridemia, liver disease, and cholelithiasis may also be contraindications to therapy.

At the Hospital for Special Surgery (53), about 90% of women eligible for estrogen therapy were reluctant to undertake it because of the perceived risk of cancer. Clearly, it is the orthopaedist's responsibility to educate the patient on relative risks and benefits of estrogen therapy. If hormonal therapy is chosen, we recommend a minimum dose of 0.625 mg of conjugated estrogen cycled with appropriate medroxyprogesterone acetate. Mammograms and gynecologic evaluations must be done at least yearly.

**Tamoxifen/SERMs**

Tamoxifen and selective estrogen receptor modulators (SERMs) such as relaxofen provide ERT-like bone benefits without the associated breast and endometrial cancer risk. Preliminary data suggest that spinal fractures decrease by 50% and the risk of breast cancer decreases similarly. There are no data regarding hip fracture.

**Calcitonin**

Calcitonin directly inhibits osteoclast function, and chronic administration may decrease the number of osteoclasts. Calcitonin is a strong antiresorptive agent particularly useful for patients with high-turnover osteoporosis who will not take estrogen or progesterone. Currently, calcitonin must be given subcutaneously by injection; in some patients, flushing accompanies injection. Although 40% of patients develop an antibody to the calcitonin, this circumstance does not preclude its use. Patients on calcitonin have shown increases in total body calcium, iliac crest bone volumes, and bone content of the lumbar spine and femoral diaphysis (21,24,25).

Most of the increase occurs in the first 6 months.

Calcitonin has been shown to decrease the incidence of vertebral fracture by 37% (91). Nasal calcitonin is similarly effective, with few or no side effects (11). Calcitonin may also be particularly useful in patients with acute recent spinal fractures, as there is evidence that it functions as a neuropeptide and has an analgesic effect. It is also helpful in steroid osteoporosis, in which it counteracts the secondary hyperparathyroidism. The usual dose is 200 units daily nasally for 18 months, with concomitant calcium and vitamin D.

**Bisphosphonate**

The bisphosphonates, particularly etidronate, have been used for decades in the treatment of Paget's disease; recently, they have been used successfully to treat osteoporosis (62,94). The cyclic use of etidronate, 400 mg/day for the first 14 days of each quarter, significantly increased bone mass by 1% to 2% per year and decreased the spinal fracture rate when compared with calcium alone (87,88). Appendicular bone mass increased less, and there was no clear effect on prevention of hip fractures. Some of the newer bisphosphonates, the so-called third-generation bisphosphonates, including pamidronate and alendronate, lead to a greater increase in spinal mass and may enhance formation and decrease resorption more effectively than the first-generation bisphosphonates such as etidronate (55). Alendronate use is supported by a large number of clinical trials using fracture as an end point (42). Like ERT, alendronate increases bone mass and decreases fracture risk for all bones by 50%. The major side effect is esophagitis. Alendronate appears to have similar efficacy on osteoporosis in men.

Prolonged use of first-generation bisphosphonates inhibits bone formation and resorption and can lead to osteomalacia, which is the reason for using short cycles. The
ORTHOPAEDIC PROBLEMS

Fractures in patients with osteoporosis may entail increased morbidity and mortality. Economic consequences of these fractures can also be quite severe. Cornell has developed the following principles guiding the management of fractures in patients with osteoporosis (14):

- Elderly patients are best served by rapid definitive fracture care aimed at early restoration of mobility and function. Often patients are in their best health on the day of the injury. If so, perform surgery at that time. Judicious medical management of patients with coexisting medical problems can minimize postoperative morbidity and mortality. Choose surgical procedures that require minimal operative time and result in minimal blood loss while providing definitive care.
- The operative procedure should allow stable fracture fixation with early weight bearing or early return of function. Intra-articular fractures should be anatomically restored, but metaphyseal and diaphyseal fractures are best managed by achieving primary stability rather than anatomic reduction.
- In osteoporotic patients, the primary mode of failure of fracture repair is failure of the bone rather than failure of the implant. Choose fracture fixation to allow stable compaction of fracture fragments and to minimize stress shielding of regional bone.
- Osteoporotic patients go through the early stages of fracture healing by endochondral repair normally. However, the last stage of remodeling is slowed in these patients. Hip fractures can remain positive on bone scan as long as 3 years. In addition, elderly patients often are malnourished at the time of injury, and their diets are deficient in calcium, calories, and protein. Administer 1,500 mg/day of calcium and physiologic vitamin D to patients in the hospital, as well as a diet sufficient in calories and protein to overcome malnutrition.
- Evaluate patients with fractures fully for the type of osteoporosis they have, and initiate treatment on the basis of the pathology.

Although not the most common osteoporotic fracture, hip fractures are the major cause of morbidity and mortality in patients with osteoporosis (45). About 32% of women and 17% of men suffer a hip fracture before age 90, and 40% of noninstitutionalized patients die within 2 years of the injury (4,30,31,35,36,40,90). A return to preinjury level of function is seen in only 25% of patients who suffer a hip fracture, and 50% of these patients have a significant social deterioration (86,88).

Other nonmetabolic causes of hip fractures have been noted. It has been suggested that the common use of tranquilizing medication in this population results in poorer reaction time and an increased incidence of falls (88,93). Hayes has suggested that only falls that result in a direct blow to the region of the greater trochanter result in hip fracture (31). Recent incidence studies by Cummings and Hayes now place falls as the primary etiology in 65% to 95% of cases (15). Osteoporosis is almost universally found in patients with hip fractures.

Femoral neck fractures are a particular problem in patients with osteoporosis because of the high incidence of nonunion and avascular necrosis. Closed reduction and internal fixation have been associated with an incidence of about 14% nonunion and 15% avascular necrosis (11). While these complications can be minimized by accurate reduction, patients with severe osteoporosis have a higher incidence of failure secondary to loss of bone fixation (3).

The basic treatment options for femoral neck fracture are closed reduction with internal fixation, and hemiarthroplasty. Hemiarthroplasty would seem an ideal procedure, as nonunion and avascular necrosis would not occur, but it is associated with its own complications (dislocation, loosening and breakage of implants, late infection). In addition, hemiarthroplasty does not provide hip function equal to that of an intact hip joint. We recommend primary hemiarthroplasty using a cemented bipolar prosthesis for patients who are physiologically 70 years of age and who are active household or community ambulators. Patients with severe osteoporosis and those with neurologic disorders who cannot comply with partial weight-bearing are also selected for hemiarthroplasty.

For patients who do not fit these criteria, perform closed reduction with internal fixation using cannulated screws, Knowles pins, or compression screws. A study from New York Hospital–Cornell Medical Center and the Hospital for Special Surgery showed that among 251 patients undergoing this procedure between 1979 and 1981, 80% of those with grades III and IV fractures had good to excellent results at 6 months when good reduction was obtained in the operating room, compared with 95% good-to-excellent results for hemiarthroplasty. The survival rate at 6 months was 96% for patients with Knowles pins and 95% with hemiarthroplasty (Fig. 131.8) (2,6).

**Figure 131.8.** Hemiarthroplasty (bipolar) for treatment of displaced femoral neck fracture.

Intertrochanteric fractures are common in patients with osteoporosis. These fractures do not have the same rate of nonunion and avascular necrosis as do femoral neck fractures, but malunion with varus and shortening in external rotation is a risk. Nail side-plate devices, such as the Jewett nail, have been associated with loss of fixation. This device is a load-bearing, not a load-sharing, device. Use of these fixators in patients with poor bone quality often results in loss of fixation or pin penetration into the joint.

Sliding hip screws are load-sharing devices that allow controlled impaction. The sliding hip screw has been our primary means of treatment of intertrochanteric fractures. Several technical points should be noted. Place the screw in the center of the femoral head to engage subchondral bone. A screw with a side-plate angle more than 140° is optimal for biomechanical reasons. New screws with extra-large threads have been introduced to improve fixation in poor-quality bone. In patients with grossly unstable fractures in which a large amount of impaction is anticipated, use short-barrel side plates (Fig. 131.9). Some authors have recommended lag-screw fixation for large posterior medial fragments to improve the stability for three- and four-part intertrochanteric fractures (48).

**Figure 131.9.** A: Intertrochanteric hip fracture fixed with sliding hip screw. B: Further impaction. Patient went on to union in this position.

Supracondylar fractures of the distal femur and fracture of the tibial plateau are also seen in patients with osteoporosis, because they occur in areas of thin cortex and abundant trabecular bone. In general, gear treatment toward producing early range of motion in the knee and quadriceps rehabilitation. In debilitated patients with limited ambulatory capacity preoperatively, or limited life expectancy, either a long-leg cast or cast-brace may be the best treatment. If surgery is necessary, the standard principles of anatomic restoration and rigid fixation apply as in any fracture.

For supracondylar femur fractures, use a 95° condylar plate or screw side plate device (Fig. 131.10). In extremely comminuted fractures, a condylar buttress

**Figure 131.10.** supracondylar femur fracture fixed with condylar plate.
plate can be substituted. Autogenous bone graft can be applied to areas of comminution. Rigid fixation will allow early knee rehabilitation, including continuous passive motion (CPM). Ideally, in a stable situation ambulation can be started, although a cast-brace may be required.

Figure 131.10. A: Supracondylar femur fracture. B: Fixation of supracondylar fracture.

Minimally displaced tibial plateau fractures that have less than 5 mm of depression and are stable on examination can be treated by a short period of knee immobilization, followed by active knee motion. No weight should be put on the site until fracture healing has occurred. CPM may be used after the injury; apply a hinged knee brace for protection. Patients with displaced fractures of more than 5 mm or with an associated varus or valgus instability require open reduction and internal fixation (66) (Fig. 131.11).

Figure 131.11. A: Tibial plateau fracture. B: Fixation of tibial plateau fracture.

A longitudinal midline incision provides excellent exposure; it is the incision of choice in elderly patients who may later need a total knee arthroplasty. Use CPM and a cast-brace postoperatively, and delay weight bearing for 8–10 weeks.

Treat fractures of the ankle in patients with osteoporosis by the same principles as for ankle fractures in younger patients. In osteoporotic bone, which often provides poor screw purchase, Rush rods or tension band techniques may be superior. Antiglide plate fixation of the lateral malleolus also offers advantages in the elderly (8,81). Pay close attention in the postoperative period to the wound. Generally, use splints for 10–14 days; keep the fracture site elevated and permit no weight bearing. Then apply a short-leg cast for 4–6 weeks, and begin joint range-of-motion and strengthening exercises.

Perhaps the most common osteoporotic fracture is the fracture of a vertebral body. In 90% of the population, radiographic evidence of a vertebral injury is discernible by age 75 (37). The classic "dowager's hump" is the result of compression and wedge fractures primarily of the thoracic and lumbar spine, resulting in kyphosis and diminished height. To maintain upper body posture, a hyperlordotic curve can develop in the lumbar spine, resulting in mechanical low-back pain.

Generally, vertebral body fractures are identified by loss of height of the vertebral body or anterior wedging of the vertebral body, in addition to clinical symptoms of pain and tenderness. Often, though, the fractures may be relatively asymptomatic and discovered only on radiograph. As previously mentioned, a patient with one isolated vertebral fracture must be fully evaluated to exclude the diagnosis of malignancy. In addition, as with all osteoporotic fractures, do a full evaluation of the underlying metabolic bone disease.

Medical treatment of osteoporosis has already been discussed, and additional orthopaedic intervention may be required. Pain may be a prominent finding in patients with vertebral body fractures, and analgesics may be necessary. Narcotic analgesics are unsuitable because of the potential for respiratory depression and the effect of sedation on the patient's ability to ambulate without falling.

Bracing or mechanical support of the spine is controversial. Nachemson (73) and others believe that bracing should be avoided, because further osteoporosis will result if the brace functions as a load-bearing device. Studies by Krag et al. suggest that corset spinal braces do not significantly reduce the load on the spine but do restrict motion (49,50). These braces may allow the patient to ambulate while restricting motion enough to minimize pain.

A total-contact orthosis probably significantly unloads the spine and is undesirable in patients with severe osteoporosis. A light hyperextension type of orthosis may be helpful in relieving pain in some patients; however, patient compliance can be a problem. In these cases, a very short period of bed rest followed by ambulation and mobilization as tolerated may be sufficient.

Osteoporotic spine fractures are rarely treated by operative means, except for the rare patient in whom significant neurologic compromise develops. Patients who suffer a high-energy type of burst fracture with a resultant unstable spine require posterior fixation.

OVERVIEW

This chapter covers the etiology of musculoskeletal infection, diagnostic options, and antimicrobial treatment. No attempt is made to discuss the specific management of individual infectious problems such as acute or chronic osteomyelitis, infectious arthritis, or infected total joint arthroplasty, because these issues are covered in Chapter 73, Chapter 133, Chapter 134, Chapter 135, Chapter 150, and Chapter 176. Nor does this chapter include information on universal precautions and protection of the health care worker.

Important issues bearing on the etiology of musculoskeletal infection include an understanding of normal human skin flora, bacterial virulence factors, antibiotic resistance, nonspecific and specific immunity factors, and immune deficiency states. Also important are the impact of surgical technique, skin preparation, and antibiotic prophylaxis.

Diagnostic evaluations involve laboratory studies including erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and the newer polymerase chain reactions (PCR). Roentgenographic imaging tools include plain x-ray studies, tomograms, computer-assisted tomography (CT scans), magnetic resonance imaging (MRI), and nuclear medicine studies (99m Tc bone scans, gallium- and indium-labeled white blood cell scans, and IgG). Culture, antibiotic susceptibility testing, and biopsy are also discussed.

Antimicrobials are discussed on the basis of their classification and properties including dosing, adverse effects, toxicities, and interactions. New antibiotic options, novel delivery systems, and issues surrounding long-term suppressive antibiotic therapy are discussed.

COMMON INFECTIONS

Postoperative Wound Infection Incisional wound infection is a relatively uncommon complication of an orthopaedic surgical procedure. Because most procedures are considered "clean," the expected incidence of infection is approximately 2%. The most common offending pathogens in these types of infection are Staphylococcus aureus and Staphylococcus epidermidis. Because of the morbidity associated with these infections, the benefits of routinely using prophylactic antibiotics are believed to outweigh the risks to the patient. These risks can be reduced by obtaining a detailed history of adverse reactions to medication. Prophylaxis may be further enhanced with a good understanding of the antibiotic sensitivities of the organisms in a given institution (24).

Cellulitis Cellulitis is a spreading infection of the subcutaneous tissues, and it is usually due to streptococci, although a significant number of cases are caused by S. aureus. Often, the patient has experienced a minor trauma, or an insect sting or bite. This event may have allowed bacteria to gain entry into the subcutaneous tissues. The findings of tenderness, erythema, and lymphangitis or lymphadenopathy will allow you to make the diagnosis. Most cases of uncomplicated cellulitis can be simply treated with oral antibiotics. Admit patients to the hospital whose cellulitis is complicated by immunodeficiency, high fever, or systemic toxicity for administration of intravenous (IV) antibiotics and observation.

Paronychia and Felon Paronychia is the most common infection of the hand and involves the soft-tissue fold that surrounds the fingernail. It is commonly caused by the introduction of S. aureus into this paronychial tissue by a hangnail, manicure instrument, or tooth. Early use of warm soaks and oral antibiotics, as well as resting of the involved digit can halt the infection. As the condition progresses, there may be a need for incision and drainage of the abscess, followed by parenteral or oral antibiotics, depending on the extent of the infection.

A felon is a subcutaneous abscess in the distal pulp of a finger or thumb. Numerous fibrous septae tether the skin to the bone and compartmentalize the pulp space; thus, a felon is composed of a series of small closed-space infections, which must be individually incised and drained. Pain and swelling in the finger develop quickly as the involved digit can halt the infection. As the condition progresses, there may be a need for incision and drainage of the abscess, followed by parenteral or oral antibiotics, depending on the extent of the infection.

Bite Injuries Injuries caused by human bites are commonly seen in the emergency room. The most common infective organisms are normal flora of the mouth such as Streplococcus viridans, Bacteroides, S. epidermidis, S. aureus, and Peptostreptococcus. Irrigate and debride bite wounds adequately, and leave them open. Direct antibiotic therapy at the most common infecting organisms.

Dog bites may harbor S. viridans, Pasteurella multocida, Bacteroides, and Fusobacterium. Treatment of dog bites may be complicated by the threat of rabies. All efforts should be made to discover the rabies status of the dog. Prophylactic antibities treatment must be considered.

Cat bites are more dangerous than those of dogs, because feline teeth allow deeper penetration of tissue and the wounds are more difficult to drain adequately. It is estimated that more than 80% of cat-bite wounds become infected compared with 5% of dog bites. In cat bites, the common infecting organisms include P. multocida and S. aureus (Table 132.1).
of the extremities (may be of concern in those patients with implanted prosthetic devices, which may become seeded during these events. The bowel and bladder also acts as reservoirs. Studies have shown that a transient bacteremia of these species occurs during dental procedures and up to 25% of the time after brushing one’s teeth. This bacteremia primary organisms of the oral flora are streptococci, micrococci, and gram-negative rods.

The flora of the nails is similar to that of skin, but in addition to bacteria, various species of fungal can also be isolated, including Aspergillus, Penicillium, Cladosporium, and Mucor. The conjunctival and respiratory mucosal flora when cultured can show Corynebacteria, Neisseriae, Moraxellae, Streptococcus, and Staphylococcus. The primary organisms of the oral flora are Streptococcus viridans and b-hemolytic streptococcal species that are often involved in periodontal disease and dental caries. Studies have shown that a transient bacteremia of these species occurs during dental procedures and up to 25% of the time after brushing one’s teeth. This bacteremia may be of concern in those patients with implanted prosthetic devices, which may become seeded during these events. The bowel and bladder also acts as reservoirs for a wide variety of disease-causing gram-negative bacilli, enterococci, anaerobes, and the gram-positive rod C. perfringens, which may be involved in gas gangrene of the extremities.

Necrotizing Fasciitis Necrotizing fasciitis is a relatively rare infection with high mortality (40%) and morbidity rates. Most cases of necrotizing fasciitis follow minor trauma or recent surgery, with the highest incidence seen among patients with small-vessel diseases such as diabetes mellitus. The clinical manifestations include extensive dissection and necrosis of the superficial and often deep fascia. The infection undermines adjacent tissue and leads to marked systemic toxicity. Thrombosis of the subcutaneous blood vessels leads to necrosis of the overlying skin. Numbness or analgesia replaces the initial local pain as the infection involves the cutaneous nerves. It is most commonly associated with Group A streptococcus but may also be the result of infection by staphylococcus, or gram-negative enteric bacteria. With careful use of bacteriologic techniques, anaerobes, such as Peptostreptococcus, Bacteroides, and Fusobacterium sp, can be isolated in 50% to 60% of cases. It is an emergency situation, and treatment involves wide surgical debridement of the infected area and administration of IV antibiotics.

Tetanus Tetanus is a potentially deadly yet easily avoidable neuroparalytic disease that is caused by the exotoxin of the gram-positive anaerobe Clostridium tetani. Treatment involves proper wound care and prophylactic treatment with formalin-inactivated tetanus toxoid. Immunization for tetanus has a well-established schedule, and indications for reimmunization can be easily determined on the basis of the wound sustained and the patient’s immunization history. Patients with no previous history of immunization or very severe wounds may benefit from the administration of tetanus immune globulin (Table 132.2).

Foot Infections Foot infections are common in patients with diabetes because of the prevalence of vascular insufficiency, neuropathy, and immune deficiency. Cultures of these infections generally reveal them to be polymicrobial in nature.

Puncture wounds of the foot through the sole of a shoe are commonly associated with Pseudomonas. Pseudomonas infection is serious and requires aggressive debridement and antibiotic therapy.

FACTORS INFLUENCING INFECTION

Numerous factors determine the incidence of infection, its progression, and ultimate response to intervention in a given patient. They can be separated into factors relating to the infecting organism, the patient, the surgeon, and the choice of optimal therapy.

BACTERIA-DETERMINED FACTORS

Normal Human Flora

Multiple factors influence the ability of bacteria to cause infection and disease. One of the most commonly neglected yet important concepts to understand is the fact that a diverse flora is associated with the normal skin, mucous membranes, and the respiratory, urogenital, and gastrointestinal mucosa from birth until death. The human body harbors numerous bacteria, with the composition of this flora remaining relatively stable within body regions during a person’s lifetime. In some instances, the flora may aid the host by competing for microenvironments with other pathogenic bacteria, but in other circumstances, if given the opportunity, these bacteria may be the actual cause of disease. The main influences determining the composition of the natural flora of the human body are pH, temperature, redox potential, and oxygen, water, and nutrient levels.

The most important normal flora to be considered in orthopedic surgical infections are skin flora. The variety of microenvironments provided by skin allows for the wide diversity of dermal flora. Different bacteria characterize the following four regions: (1) the axilla, perineum, and toe webs; (2) hand, face, and trunk; (3) upper arms and legs; and (4) fingernails and toenails. Sites with more potential for occlusion, such as the axilla or perineum, harbor more bacteria than open areas like the arm or trunk. It is believed that the increased moisture, temperature, and skin surface lipids allow for the higher numbers of organisms. These more occluded regions may also have higher levels of gram-negative bacteria.

S. epidermidis is the most abundant bacteria of the skin surface, comprising up to 90% of the aerobic flora in some areas. S. aureus is found most abundantly in the nasal cavity and perineum, with levels ranging from 10% to 40%. Its prevalence rises to 67% on vulvar skin. In those individuals with dermatologic conditions, such as psoriasis or atopic dermatitis, the prevalence may be more than 80%. Propionibacteria are common in areas rich in sebaceous glands and are associated with trichomycosis axillaris and acne vulgaris. Propionibacterium acne is the most common offending species. Other bacteria seen less commonly on the skin include streptococci, micrococi, and gram-negative rods.

The flora of the nails is similar to that of skin, but in addition to bacteria, various species of fungal can also be isolated, including Aspergillus, Penicillium, Cladosporium, and Mucor. The conjunctival and respiratory mucosal flora when cultured can show Corynebacteria, Neisseriae, Moraxellae, Streptococcus, and Staphylococcus. The primary organisms of the oral flora are Streptococcus viridans and b-hemolytic streptococcal species that are often involved in periodontal disease and dental caries. Studies have shown that a transient bacteremia of these species occurs during dental procedures and up to 25% of the time after brushing one’s teeth. This bacteremia may be of concern in those patients with implanted prosthetic devices, which may become seeded during these events. The bowel and bladder also acts as reservoirs for a wide variety of disease-causing gram-negative bacilli, enterococci, anaerobes, and the gram-positive rod C. perfringens, which may be involved in gas gangrene of the extremities.
Bacterial Virulence Factors

Bacterial virulence, defined as the pathogenicity of a microorganism, is affected by such factors as the number of infecting organisms, route of entry into the body, and virulence factors that bacteria have evolved to invade, cause disease, and evade the host's defenses. Virulence can be measured experimentally by determining the dosage of bacteria required to cause death or disease in a given species. These calculations refer to the inoculum required to cause death or symptoms in at least 50% of the population, the so-called lethal dose (LD50) or effective dose (ED50) respectively.

Virulence factors may be specific to each bacterial species or may be found in a broad range of organisms. One such factor is the presence of pili or fimbria that allow bacterial adherence to host cells or aid the bacteria in escaping host defenses. The pilus of Streptococcus pyogenes and Escherichia coli allow the organisms to attach to the mucosa, whereas the pilus of Neisseria gonorrhoeae also function as an inhibitor of phagocytosis.

Bacterial cell surface receptors also play a part in the disease process. S. aureus, Yersinia, and S. pyogenes isolated from patients suffering from septic arthritis possess a cell surface collagen receptor. Rickettsia sp and Mycobacterium tuberculosis invade host cells and, as obligate or facultative intracellular pathogens, avoid the host immune response.

Capsule formation has long been recognized as a bacterial protective mechanism. These capsules act to interfere with opsonization by immunoglobulins, phagocytosis, and intracellular killing of the bacteria. There are numerous bacteria that produce such capsules including Streptococcus pneumoniae, E. coli, Bacteroides, Salmonella, and Haemophilus influenzae. Protein A, expressed by S. aureus, is antiphagocytic and binds to the Fc portion of IgG, preventing complement binding and opsonization. Protein M of S. pyogenes inhibits phagocytosis.

Endotoxin is most commonly produced by gram-negative organisms. It is a naturally occurring bacterial outer-cell membrane component that has systemic effects on the host, causing a generalized sepsis that can progress to shock. Exotoxins are specifically produced for release by bacteria, generally exerting their effects over a limited site of action or on particular cell types or receptors. There are multiple classes of exotoxins, including neurotoxins, cytotoxins, and enterotoxins.

The classic neurotoxin is that of C. tetani that affects only the inhibitory neurons in the central nervous system (CNS). The result is unopposed firing of motor neurons, leading to violent muscle contractions and a spastic paralysis known as tetanus. S. aureus produces a leukocidin that destroys polymorphonuclear cells as well as an a-toxin that functions to cause lysis of monocytes and platelets, resulting in the formation of pus and abscesses.

Other bacteria secrete enzymes as a virulence factor. Pseudomonas aeruginosa secretes elastase, collagenase, and lecithinase, as well as an exoprotease that cleaves and inactivates immunoglobulins. S. pyogenes produces the clot-lysing enzyme streptokinase, as well as the enzymes streptolysin O and S. IgA protease, produced by S. pneumoniae, N. gonorrhoeae, and H. influenzae, destroys the secretory immunoglobulins.

A specific virulence factor related to the pathogenesis of prosthetic joint infections involves adhesion of the organism to the biomaterial. The implant elicits a host response that results in the coating of the prosthetic material and potential pathogen in a layer of proteins including fibronectin, vitronectin, collagen, and fibrinogen. This "extracellular slime" acts to bind the organism and foreign body together. The adhesion of S. aureus to biomprothetic materials is also mediated by adhesin molecules belonging to the microbial surface components recognizing adhesive matrix molecules (MSCRAMM) family of microbial cell surface proteins. The organism further encases itself in glyocalyx that probably includes glycerol techoic acid. This extracellular slime isolates bacteria from the immune surveillance of the host. Furthermore, the glyocalyx stimulates monocytes to produce prostaglandin E2, which acts to inhibit T lymphocyte proliferation, B-lymphocyte blastogenesis, and immunoglobulin production. It interferes with white cell chemotaxis and degranulation, as well as immunoglobulin opsonization, and inhibits antimicrobial therapy from locally reaching effective levels to exert their actions.

Antibiotic Resistance The final microbial factor that influences the course of infection is the presence of antibiotic resistance. The issue of resistance is an ever-growing problem in medicine and is discussed in detail as it relates to each specific antibiotic.

PATIENT-DETERMINED FACTORS

The human immune system is charged with resisting the onslaught of invading organisms and keeping the body free from infection. This process involves the two distinct arms of the immune system, innate or nonspecific immunity and acquired or specific immunity (Table 132.3).

**Table 132.3. Systemic and Local Factors That Affect Host Response to Infection**

**Innate Immunity**

Innate immunity is based on the normal physical and physiologic barriers of the human body, as well as the inflammatory reactions that begin once these barriers are compromised. This nonspecific immune system protects from all invasion nondiscriminately.

**Physical Barriers** Innate immunity starts at the simplest level of the physical barrier of the skin and mucous membranes. These surfaces provide an effective barrier to the entry of most microorganisms. In addition, the sebaceous glands, associated with the hair follicles, produce sebum, lactic and fatty acids, maintaining the skin pH between 3 and 5, inhibiting the growth of most bacteria. Even small breaks in the skin resulting from wounds or abrasions are potential routes for infection. Biting insects harboring pathogenic organisms may also introduce these pathogens subcutaneously or systemically as they feed. This is the mechanism of spread for such diseases as malaria, bubonic plague, and Lyme disease.

**Physiologic Barriers** Physiologic barriers include lysozyme, interferon, and the complement system. Lysozyme enzymatically cleaves bacterial cell wall peptidoglycan and is capable of killing invading bacteria. Interferon exerts systemic effects that generally induce an antiviral state throughout the entire body. Complement is a group of serum proteins circulating in an inactive proenzyme state. Once activated, the cascade amplifies a nonspecific immune reaction that ultimately destroys the invading organism.

**Phagocytosis** Nonspecific phagocytosis is mediated by antigen-recognizing cells of the immune system that are on constant surveillance. Once confronted by any foreign particle or organism, these cells, best characterized by macrophages, internalize these particles and degrade them through lysosomal enzymes into macromolecular pieces. These pieces can then be presented to lymphocytes to begin the process of developing acquired immunity.

**Inflammation** The final and most important aspect of innate immunity is the inflammatory response to local tissue damage. The four cardinal signs of inflammation—rubor, tumor, calor, and dolor—have classically described this response. The events taking place during inflammation are (1) local tissue damage, (2) vasodilation, (3) increased capillary permeability, and (4) an influx of phagocytic cells. These responses are mediated by the release of local inflammatory mediators such as histamine, kinins, prostaglandins, leukotrienes, and chemotactic factors.

**Acquired Immunity**
The acquired immune system is composed of humoral and cell-mediated responses. Unlike innate immunity, the acquired immune system exhibits specificity, diversity, memory, and self and non-self-recognition. A discussion of the mechanism of this specific immunity is beyond the scope of this chapter; it is important, however, to understand the factors that may affect the ability of the body to mount an adequate immune response.

States of Immune Compromise In order to fight infection, the body must have functional reticuloendothelial and polymorphonuclear cells, as well as competent B and T lymphocytes. Patients with deficiencies in any of these cell lines are particularly vulnerable to infection. Deficiencies may be present in patients with neoplasia involving the bone marrow, those receiving certain medications (including patients taking corticosteroids or immunosuppressives in the case of transplant or rheumatoid arthritis), and patients with systemic illnesses such as sickle cell disease. Tannenbaum et al. (50) followed the clinical progress of 19 patients who had undergone both transplant and arthroplastic procedures. Their findings suggested that patients who had undergone orthopaedic procedures before transplant surgery had the same rate of infection as the native population. Paths have found orthopaedic procedures following transplantation, however, were at a significantly higher risk for developing infection in the prosthetic joint. Their study concluded that this increased risk was most evident in those patients whose immunosuppressive protocol included the use of cyclosporine A (50).

The prevalence of human immunodeficiency virus (HIV) infection continues to spread in the United States and throughout the world. The virus has a tropism for CD4, or so-called “helper” T lymphocytes, infecting and ultimately destroying them. The CD4 lymphocytes play a crucial role in orchestrating the activation and actions of both humoral and cell-mediated immunity. When patients have lost significant activity of their CD4 cells, they are no longer immunocompetent and are given the diagnosis of acquired immunodeficiency syndrome (AIDS). These patients are at risk of developing opportunistic infections as well as infections seen in healthy individuals. Corticosteroid use, lymphomas, nutritional deficiencies, obesity, uremia, and widespread radiation therapy, as well as the other factors, may all be causes for immunocompromise in patients. In the case of patients with longstanding diabetes, vascular compromise along with neuropathy can allow small wounds in the distal lower extremities, in the absence of proper care and adequate inflammatory and immune responses, to become limb-threatening infections.

Patients with diabetes, alcoholism, patients on cytotoxic medications, and those with hematologic malignancies may develop neutropenia, with absolute neutrophil counts below 500 cells/ml. At this point, such patients are vulnerable to infections from S. aureus and gram-negative enterobacteria, as well as certain fungi. These patients may not have high fever or appear toxic because of their lack of immune response. The index of suspicion should be very high in such patients, and a fever of 38°C (100.5°F) or higher should warrant a thorough evaluation.

Patients with congenital or qualitative defects of their humoral or complement systems are vulnerable to infection as well, particularly with encapsulated organisms such as N. meningitidis, H. influenzae, and S. pneumoniae. The same holds true for patients who have undergone splenectomy. Nonfunctional complement also predisposes for infections from S. aureus and gram-negative enterobacteria.

Nutritional Status Malnutrition may affect wound healing, humoral and cell-mediated immunity, serum complement levels, and neutrophil chemotaxis and bactericidal activity. The basal metabolic requirements of patients who have undergone major mechanical trauma or severe burns may rise to 200% of normal levels.

The most important component of a patient’s nutritional evaluation is the history and physical examination. Measure weight and height, assess caloric intake, and evaluate medical conditions that may affect nutritional status. On physical examination, look for evidence of weight loss, loss of subcutaneous fat, muscle wasting, and the presence of edema or ascites. Anthropometric measurements such as skin-fold thickness and muscle circumference are often not useful. Clinical palpation of the triceps muscle, however, can often provide an excellent estimate of nutrition, because extensors tend to lose muscle mass faster than flexors.

Laboratory investigation may also contribute to nutritional evaluation. Measurement of visceral proteins, renal and liver function, serum electrolytes and minerals, and hematologic evaluation, as well as delayed cutaneous hypersensitivity testing, may all play a role in developing the overall nutritional assessment of a patient. Malnourishment has been defined in the past by laboratory values of serum albumin levels below 3 to 4 mg/dl, serum transferrin below 150 mg/dl, and total lymphocyte counts below 1500 cells/mm³. Additionally, the absence of significant immune reaction to skin testing may indicate a malnourished state.

Distant Infections Finally, the presence of infection at a distant site at the time of surgery has been associated with prosthetic joint infections. Patients with such infections may continue to have episodes of transient bacteremia, seeding the entire body with bacteria, and increasing their risk for developing infection. Screen patients thoroughly for the presence of pulmonary, genitourinary, skin, and dental infections preoperatively. Treat and eliminate the infection before proceeding with any orthopaedic procedures.

SURGEON-DEPENDENT FACTORS

Surgeon Technique The actions and decisions the surgeon makes in treating a patient play a tremendous role in the development and subsequent progression of infection. When treating a patient with an open wound after trauma or infection, be certain to irrigate the wound adequately, removing the greatest load of bacteria and foreign debris possible. At the same time, debisce the wound well, and remove all nonviable tissue, making certain that the remaining tissue has an adequate blood supply. In the case of open fractures, the use of prophylactic antibiotics with early irrigation and debridement can minimize the risk of an infection that may jeopardize healing. The length of surgery may also influence the incidence of infection. In addition, orthopaedic techniques, such as reaming, can disrupt local blood supply and alter host-cell, humoral factor, and antibiotic penetration to the site.

In addition, foreign materials such as polymethylmethacrylate cement (PMMA) can contribute to the potential for infection. PMMA significantly increases the likelihood for infections with S. epidermidis and S. aureus. In vitro studies have shown the toxicity of PMMA monomer on the bactericidal serum factors, terminal complement components, phagocyte function, and immune cells. PMMA may become toxic, and reach toxic concentrations surrounding implanted prostheses. When closing the wound, it is important to eliminate dead space, have satisfactory drainage of hematomas, and provide adequate soft-tissue coverage.

Skin Preparation Preparation of the skin for surgery can play a role in the incidence of infection, because infection may occur whenever the protective barrier of the skin is broken. Proper preparation of the skin before incision can decrease the risk of contamination significantly (7).

The purpose of preoperative skin preparation is to remove the soil and transient flora found on skin, to reduce resident microbial counts to subpathogenic levels in a short period of time with the least amount of tissue irritation, and to inhibit the rapid rebound growth of microorganisms. Although the normal flora of the skin and hair can never be eradicated, the total number of organisms can be markedly reduced through the use of agents such as iodine idophors, alcohol, hexachlorophene, and chlorhexidine. These preparation agents have excellent activity against gram-positive bacteria and good activity against gram-negative bacteria and fungi, reducing microbial activity 100-fold within minutes. It must be kept in mind that the sebaceous glands and hair follicles of normal skin where bacteria reside and multiply can never be sterilized because of the poor penetration of these agents.

The transient skin flora is easier to remove than the resident flora that may be attached or absorbed into the epidermal layers. Studies have measured that approximately 20% of resident skin flora is not removed by standard preparation techniques. A recent study comparing clean and sterile prep kits showed no difference between the efficacy of either kit, a fact that has significant financial implications for medical centers. The cost of prep kits assembled in the hospital is significantly less than that of disposable kits provided by vendors. When necessary, perform hair removal in the operating room. Studies have shown that shaving of the operative site the night before surgery can produce conditions optimal for the reproduction of bacteria, increasing the risk of infection (43). Operating Room Environment Despite the use of ultra-clean air, airborne bacteria in the operating room environment remain a source for contamination. Bacteria may enter the wound directly or indirectly through gloves or instruments that may become contaminated during skin preparation and patient draping. These bacteria are believed to be mostly gram-positive and shed by personnel in the room, particularly during periods of increased activity. Conventional operating rooms may have as many as 10 to 15 bacteria per cubic foot. Lidwell reported the development of infection following 1.5% of total hip arthroplasties performed in conventional operating rooms and only 0.6% of procedures performed in ultra-clean air operating rooms. Sir John Charnley advocated the use of rapid air-change systems, along with multiple ultraviolet air sterilizers, to reduce the total number of airborne bacteria. Studies have found the number of airborne bacteria can be reduced by approximately 50% in such ultra-clean air operating rooms and, perhaps again by 50% with the use of body exhaust suits. Other studies have shown no benefits to the use of ultra-clean air, and one series examining the use of horizontal laminar air flow actually revealed an increase in the rate of infection in total knee arthroplasty (6.41.45.51.56).

Rates of infection have been found to be directly related to airborne bacterial levels. Standards have been recommended for ultra-clean air operating rooms: fewer than 10 colony-forming units per cubic meter (CFU/m³) within 30 cm of the wound and 20 CFU/m³ at the level of the operating table within the remaining clean-air enclosure (6.45).

A recent study examined the airborne bacterial counts during skin preparation and patient draping. Airborne bacterial counts were found to be 4.4 times higher during prepping and draping of the extremity with an unscrubbed, ungowned leg holder, and 2.4 times higher with a scrubbed and gownned leg holder as compared with intraoperative levels. Another study examined the levels of bacterial contamination in two layers of latex gloves during operative procedures. It was found that the outer
glove used exclusively for draping is the most significantly contaminated, and changing this outer glove at appropriate times during surgery greatly minimizes the rates of contamination (34). The use of ultraviolet light in operating rooms has also been shown to decrease the incidence of wound infection by reducing airborne bacteria.

**Antibiotic Prophylaxis**

The issue of administration of prophylactic antibiotics is another important decision for the treating surgeon. The incidence of infection in clean surgery should be less than 2%. For clean surgery that involves the implantation of foreign material, grafts, polymethylmethacrylate cement, or prosthetic devices, prophylaxis is well accepted and justified, because this practice provides benefits that outweigh the expected risks. Prophylactic antibiotics should also be used in cases of major devascularization, impaired host defenses, or suspected wound contamination.

Ideally, any prophylactic antibiotic given to a patient should be bactericidal, have low toxicity and good tissue penetration, be low in cost, and effective against the most commonly found oral or oral cavity organisms. Staphylococcus aureus, S. epidermidis, and other coagulase-negative staphylococci, as well as Pseudomonas aeruginosa, are the most common pathogens involved in total joint prosthetic infections and 70% to 90% of wound infections in clean surgery. Gram-negative bacilli are involved to a much lesser extent. First-generation cephalosporins have been favored in this country for a variety of reasons. They are nontoxic, inexpensive, and effective against the potential infective organisms. The administration of antimicrobial agents for a short duration (24 to 48 hours) postoperatively is effective in preventing infection (35).

Intravenous cefazolin, given as 1 g within 2 hours of entering the operating room has been shown to be effective in this capacity. Ideally, the infusion should be completed 30 minutes before surgery to ensure adequate antibiotic levels at the time of skin incision. An additional 1 g dose should be administered if the duration of surgery is longer than 4 hours. Cefazolin 500 mg every 8 hours can be continued for 24 hours postoperatively.

In institutions with a high incidence of methicillin-resistant S. aureus or coagulase-negative staphylococci, vancomycin alone or in combination with another agent, such as gentamicin, has been shown to be effective. Patients with a history of severe allergic reaction (urticaria, angioedema, anaphylaxis) to a penicillin or cephalosporin should receive 1 g of vancomycin 2 hours before incision and every 12 hours thereafter for 24 hours. Recent studies investigating prophylactic use of the glycopeptide antibiotic teicoplanin against methicillin-resistant staphylococci species in patients unable to tolerate vancomycin have shown it to be as efficacious as any other regimen (31,37,44,47,59).

Alternatively, the prophylactic use of antibiotics in cemented arthroplasty as well as antibiotic-impregnated polymethyl methacrylate beads has been shown to be effective in reducing the risk of infection. Jøsefsson et al. (32) followed a prospective randomized group of 1688 consecutive total hip arthroplasties comparing the use of gentamicin-impregnated bone cement with systemic antibiotics. They found a decreased risk of deep infection in those patients with antibiotic-impregnated cement, but this effect was limited to the first year after operation.

Espenhaug et al. (33) retrospectively looked at 10,905 total hip arthroplasties performed in Norway from 1987 to 1995. They compared patients who had received no prophylactic antibiotics, systemic antibiotic prophylaxis only, cement antibiotics prophylaxis only, and both systemic and cement antibiotic prophylaxis. The lowest rate of revision arthroplasty was found among those patients who had received both systemic and cement antibiotic prophylaxis. Those receiving only systemic antibiotic prophylaxis had a revision rate 4.3 times higher, those with only antibiotic cement bone 6.3 times higher, and those with no prophylaxis having a rate of revision surgery 11.3 times higher (6.8,12,19,51,55).

Antibiotic-impregnated cement beads have been used extensively in the management of open fractures and chronic osteomyelitis (42). These beads have been found to be cheaper than systemic antibiotics yet provide the same efficacy. They are able to keep local antibiotic concentration at levels that would be toxic systemically (29). Keating et al. (23) showed a decrease from 16% to 4% in infection rates among open tibia fractures. Cho et al. (19) followed 54 patients with chronic osteomyelitis of the long bones treated with local antibiotics and bone grafting an average of 4 years, finding that 55% of these patients were completely free of infection.

The use of antibiotic prophylaxis in arthroplasty patients who undergo dental procedures is controversial. A recent survey has shown that a majority of orthopaedists (n = 44) and dentists (n = 30) believe that patients with prosthetic joints should receive prophylactic antibiotics before dental procedures (81% and 46%, respectively) (47). Three approaches have been outlined in the literature.

The first approach does not recommend prophylactic antibiotic use based on the cost, the adverse effects from antibiotic agents, the potential for the emergence of antibiotic resistance, and the lack of a clear cause-and-effect relation. Others suggest routine prophylaxis before dental and other procedures known to cause transient bacteremia for at least 2 years after arthroplasty. Yet others recommend the use of prophylaxis only in those patients with conditions that predispose for infection (27,53).

Ainscow and Denham (1) reported on 1,000 patients who had undergone 1,112 joint replacements and were followed an average of 6 years. Their arthroplastic procedures were performed between 1966 and 1980. The patients in this series were never advised to take antibiotic prophylaxis before dental or surgical procedures. Of these 1,000 patients, only three were found to have developed prosthetic joint infections, and two of these patients suffered from rheumatoid arthritis. Waldman et al. (56) retrospectively looked at 3,490 patients who had had total knee arthroplasty between 1982 and 1993. Of these patients, 62 developed late infections of the prosthetic joint. Of these cases, seven were strongly associated with prior dental procedures, representing 11% of these late infections. The study concluded that the majority of infections after dental procedures occurred in those patients with systemic illnesses such as rheumatoid arthritis and diabetes mellitus.

When prophylaxis is used for dental procedures, an oral first-generation cephalosporin is an appropriate choice because its antimicrobial spectrum includes most oral and oral cavity organisms. Cephalexin 1 to 2 g 1 hour before the procedure and 0.5 to 1 g at 4 to 6 hours is recommended. Alternatively, 3 g of amoxicillin 1 hour before the procedure and 1.5 to 6 g hours after the initial dose is effective as well. Patients with allergy to penicillin should receive 600 mg of clindamycin 1 hour before the procedure and 6 hours later or erythromycin 0.5 to 1 g 1 hour before the procedure and 0.5 g 4 to 6 hours after the first dose.

**Antibiotic Irrigation**

Antibiotic irrigation is commonly used in orthopaedic procedures, although its true value has never been established. In vitro systems have shown that colony counts of S. aureus, S. epidermidis, E. coli, and Pseudomonas sp can be reduced 12% to 56% with saline irrigation alone. Several studies have shown a decrease in colony counts in wounds and a decrease in infection rates for general surgical procedures with the use of antibiotic devices. It has been shown, however, that the use of power irrigation increases the removal of bacteria by a factor of at least 100 over bulb-syringe irrigation of the same volume, regardless of the solution used (5,25).

Topical antibiotics used in irrigation should have a wide spectrum of activity and have low toxicity. The addition of polymyxin, bacitracin, neomycin, or a combination of these agents is most effective for this purpose (19).

**DIAGNOSIS OF INFECTION**

**SIGNS AND SYMPTOMS**

In the initial evaluation of orthopaedic infections, the patient's history plays a key role in guiding further diagnostic procedures and what intervention is most suitable. A history of systemic illness or medication use that may lead to immune depression are important clues as to the environment in which an infection has developed and what microorganisms may be involved. An history of prior surgery, infections at other sites, open fracture, or instrumentation can also point to a likely etiology of infection.

The symptoms classically associated with most infections, such as fever, chills, redness, nausea, swelling, and tenderness, may not be present in the context of an orthopaedic-related infection. The most reliable symptom in these situations is pain in the affected region, but this finding may be very subtle and easily missed.

In addition to pain, other symptoms that may be present include erythema, warmth, induration, tenderness, and swelling. The pain from an infected joint often is described as being constant or worsening at night. Patients may also have a decrease in range of motion of the adjacent joint. This decrease may be greater than 50%. The sensation of warmth around the joint may be the result of inflammation or infection. The presence of erythema can be difficult to assess. It is more readily detected over the bony prominences of the joint. It may be absent in cases with marked swelling of the joint or extreme tenderness.

**LABORATORY INVESTIGATION**

The first diagnostic procedures undertaken usually consist of a complete blood count (CBC), ESR, and CRP. In evaluating the CBC, the classic finding of a leukocytosis (a white blood cell count greater than 12,000) is associated with the presence of infection. This finding may not be consistent, especially in infections with a more indolent course. When leukocytosis is present, however, the differential cell count will show an increase in the relative number of neutrophils, as well as a shift to more immature polymorphonuclear cells in circulation.

The ESR is a widely used test in orthopaedic practice. It is not a specific test for infection and may be elevated in a number of systemic conditions such as advanced age, pregnancy, morbid obesity, and while a patient is using certain medications such as heparin and oral contraceptives. It is also elevated in a variety of pathologic conditions including infection, inflammation, collagen vascular diseases, recent surgery or fracture, certain malignancies, myocardial infarction, gastrointestinal, thyroid, and...
and renal diseases (11). The ESR reflects an increase in the acute-phase reactants produced by the liver in response to inflammation or infection.

Fibrinogen has been found to be the strongest promoter of the aggregation of erythrocytes, followed by other serum proteins. These positively charged proteins coat red blood cells (RBC), which normally repel each other because of their negative surface charges. The coated RBCs assume rouleaux formations and settle in the patient’s blood sample, with the rate measured as the ESR in millimeters per hour. Normal values by the Westergren method are less than 16 mm/hour for men and 25 mm/hour for women (11).

As many as 85% to 100% of patients with lumbar disc space infections, 84% to 100% of patients with proven infection about a total hip replacement, and 71% to 97% of children with hematogenous osteomyelitis have an elevated ESR (49). The ESR has been found to rise within 2 days of infection in children with infectious arthritis of the hip. The value of ESR is in following the response of infection to therapy through serial observations. Return of the ESR to normal may take many weeks, despite effective treatment of the infection.

CRP is another acute-phase reactant produced by the liver that is also a nonspecific marker of inflammation and infection. Its temporal relationship to infection, however, makes it a much more useful tool in the diagnosis of infection as well as its response to intervention. Levels of CRP rise within 6 hours of infection, reaching their peak within 48 hours, and fall to near-normal levels within 1 week of proper intervention (26).

Other laboratory investigations in the acute setting may include a cell count and Gram stain of joint fluid or localized collection aspirates. These immediate procedures can determine the presence of septic arthritis as well as quickly yielding a likely pathogen. Cell counts greater than 100,000 with a differential greater that 75% neutrophils increases the likelihood of infectious arthritis.

RADIOTOGRAPHIC INVESTIGATION

Begin with plain roentgenograms of the affected region. These images may show soft-tissue swelling, localized bone destruction, periosteal thickening, or loosening of fracture fixation hardware or total joint arthroplasty. The findings of bone destruction are rarely present until 2 to 3 weeks into the course of an infection, after a significant proportion of bone matrix has been lost. The value of such plain films is limited but can be helpful in following the course of a patient’s illness. If the suspicion of infection remains high even after this initial evaluation, the use of other imaging modalities that are able to detect disturbances of normal soft-tissue architecture, joint inflammation, or the presence of fluid collections may be necessary.

Although CT can be used to visualize effectively the bone and soft-tissue architecture of an axial and appendicular skeleton, one disadvantage is the scatter phenomenon that occurs when metal is present in or near the area of bone visualized. This scatter results in a significant loss of image resolution (38,49).

MRI has developed a tremendous role in orthopaedic surgical practice, mainly because of its superior ability to evaluate soft-tissue structures. Any infectious or inflammatory process produces localized edema in the affected area, which may be readily detected by T2 images. The fat of the marrow cavity that normally appears bright on T1WI becomes hyperintense as its intensity increases on T2WI. This finding reflects the replacement of the marrow fat with edema and inflammatory cell infiltrates. MRI may also detect bony destruction earlier than either plain x-ray studies and CT scans, because these signal changes represent the earlier processes of bone destruction that may not be visible by conventional radiographic studies. As with CT scans, metallic implants in the region of interest may produce focal artifacts, thereby decreasing the usefulness of the image (38,49).

Conventional tomography is useful for identifying sequestra and subtle hardware loosening in cases of osteomyelitis or involvement of subchondral bone in septic arthritis. Ultrasound can be used to localize abscesses or fluid collection and may aid in its proper drainage. Arthrography can be used in cases of infectious arthritis after initial synovial fluid samples have been taken. The contrast material once visualized allows determination of whether the joint was properly aspirated.

Radionuclide scanning plays a significant role in the diagnosis of infection. Contrary to the previously discussed imaging modalities, which give structural or anatomic representations of the patient, radionuclide scanning attempts to deliver functional or physiologic information. Radionuclide scanning cannot directly show infection or the structural changes that may be associated, but it can reveal inflammatory processes throughout the body and the bone’s attempt to heal. It is for this reason that radionuclide scanning has lower specificities in differentiating infection, because any source of inflammation or bone turnover can yield a false-positive result (26).

The three radionuclide tests classically used in the detection of infection include technetium 99m, gallium citrate, and indium-labeled leukocyte scans. Technetium 99m is by far the most commonly employed bone-scanning procedure and depends on uptake of the technetium by active osteoblasts. Any physiologic process that causes rapid turnover of bone appears as an increased uptake on the technetium bone scan, including infection, inflammation, metastatic tumor, degenerative joint disease, and posttraumatic and posttraumatic changes. Phosphonates reflects areas of minimal uptake of isotope and may be associated with decreased area blood flow, certain tumors, vasospasm, and impingement of the local blood supply by soft-tissue swelling.

Technetium 99m is usually administered as part of a three-phase bone scan that acts to improve the overall specificity of the test. The three phases consist of the flow phase, the equilibrium phase, and the delayed phase. The initial flow phase reflects blood flow throughout a region and large vessel patency. The equilibrium phase shows the passage of technetium into the smaller vessels of a given area and its subsequent diffusion throughout the tissues, revealing the relative blood supply to that area. The delayed phase of bone scanning is measured at a time of 3 to 4 hours after injection, when most of the remaining isotope has been taken up by osteoblasts.

By interpreting the findings at the various phases of bone scanning, you can determine the true location of increased physiologic activity. Osteomyelitis will show increased uptake of technetium 99m at flow, equilibrium, and delayed phases of bone scanning. Conversely, in the case of cellulitis, the findings at initial flow and equilibrium phases show increased activity but low or normal activity at the delayed phase. At the same time, osteoarthritis shows decreased uptake of isotope at initial flow and equilibrium phases but increased uptake at the delayed phase (32,33).

Indium-111 can be added to the patient’s incubating leukocytes in vitro. These cells are then reinjected into the patient, with imaging taking place 24 to 48 hours later. When a focal area of bone shows increased uptake relative to the surrounding bone, the scan is considered positive. Indium scanning has found a significant role in the diagnosis of acute osteomyelitis. However, in the presence of chronic infections, in which the predominant inflammatory cell type is lymphocytic, indium has a much lower sensitivity.

Indium-labeled leukocyte scintigraphy has been found to be 100% sensitive in the diagnosis of acute osteomyelitis and 60% sensitive in chronic osteomyelitis. A negative indium scan usually means that osteomyelitis is not present. Combining the indium scan with a technetium 99m scan can increase the specificity of the test. A number of conditions including fractures, arthritis, osteosarcoma, eosinophilic granuloma, pigmented villonodular synovitis, and neuroarthropathic arthritis have been found to show false-positive results on indium-111—labeled leukocyte scans (20,30,58).

Gallium citrate is believed to be taken up directly by leukocytes, thus reflecting the increased numbers of white blood cells that migrate into infected areas. It was hoped that the use of gallium citrate, when used in concert with technetium 99m scanning, could distinguish infection from other processes. Despite the initial promising results, sequential technetium-gallium scanning has demonstrated only 50% sensitivity, 78% specificity, and an accuracy rate of only 62% in the detection of low-grade musculoskeletal sepsis. These values are far inferior to the 83% sensitivity, 94% specificity, and 88% accuracy found with indium-111—labeled leukocyte scanning (46). A newer radionuclide imaging modality involves indium-111—labeled monoclonal immunoglobulin directed toward granulocyte cell surface antigens (Leukoscan). Becker et al. (4) performed scintigraphy in 53 patients at 1 to 6 hours and at 24 hours after injection of the labeled antibody. The overall sensitivity of Leukoscan and indium-111—labeled leukocytes was found to be 90% and 63.9%, respectively, the specificity the ESR 84.6% and 76.5%, respectively, and the accuracy 87.9% and 81.3%, respectively. Hakkila et al. (13) prospectively compared the efficacy of Leukoscan, indium-111—labeled white blood cell scabs, and technetium 99m bone scans in diagnosing 74 patients with suspected musculoskeletal infections. Their findings showed a sensitivity of 93%, 85%, and 92% for Leukoscan, indium-111—labeled white cells, and technetium 99m bone scans, respectively. Specificity was 89%, 75%, and 52%, and accuracy was 90%, 79%, and 74%, respectively.

CULTURE INVESTIGATION

The diagnostic modalities discussed thus far show the physiologic and structural changes caused by infection. These modalities, however, are not capable of giving an actual bacteriologic diagnosis that can aid in developing a treatment plan and proper choice of antibiotic chemotherapy. By properly using the laboratory evaluations available, the surgeon can isolate the responsible pathogen and determine its susceptibility to antibiotics (3).

Superficial wound or sinus tract cultures are seldom useful because they are usually polymicrobial and generally reflect the normal flora of the skin in the area. Mousa (38,39) prospectively compared sinus tract cultures with those obtained intraoperatively. The samples were found to be of value provided that they were obtained by deep probing of the tract and aspiration with a syringe. Swabbing of the sinus tract as well as the findings of S. epidemidis were found to be unreliable in the diagnosis. Of the 115 operative samples taken, 102 sinus tract isolates were identical to the operative cultures, with a specificity of 95.7% and predictive value of 90.3%. Lee (29)
The natural penicillins, penicillin G (benzylpenicillin) and penicillin V (the phenoxymethyl derivative), are very similar in their antimicrobial spectrum for aerobic expressed classes of autolysins seem to be responsible for the cidal action of b-lactam antibiotics. Synthesis, and as such, each b-lactam antibiotic may have different affinities for selected PBP. Once the formation of the bacterial cell wall is inhibited, two normally the enzymes that bind to penicillins are collectively referred to as penicillin-binding proteins (PBP), because their initial identification was based on their ability to bind to penicillins. Penicillin-binding proteins (PBP) are enzymes that are crucial for the synthesis and maintenance of bacterial cell walls. They catalyze reactions that result in the cross-linking of the peptidoglycan network, which provides structural integrity to the cell wall.

Once these molecules are donated by the lipid carrier and oriented, transpeptidase enzymes cross-link the peptide of the new GlcNAc-MurNAc moiety with that of another. The key targets of the penicillins in this process are the transpeptidases. By binding tightly to the active site of these enzymes, they inhibit the cross-linking of the cell wall components and reduce the overall tensile strength these cells need to resist osmotic lysis.

The enzymes that bind to penicillins are collectively referred to as penicillin-binding proteins (PBP), because their initial identification was based on their ability to bind to penicillins. The PBP are a diverse group of transpeptidases and carboxypeptidases that are involved in various aspect of cell wall synthesis, and as such, each b-lactam antibiotic may have different affinities for selected PBP. Once the formation of the bacterial cell wall is inhibited, two normally expressed classes of autolysins seem to be responsible for the cidal action of b-lactam antibiotics.

The nucleus of this molecule is the chief structural requirement for biologic activity, and any chemical or metabolic alteration of this portion causes a loss of all antimicrobial activity. Penicillins consist of a thiazolidine ring coupled with a b-lactam ring, to which is attached a side chain.

The b-lactam antibiotics are the most commonly prescribed agents in the treatment of infections of bones, joints, and soft tissue. Included in this class are the penicillins, cephalosporins, carbapenems, and monobactams. Penicillins consist of a thiazolidine ring coupled with a b-lactam ring, to which is attached a side chain.

The classic methods for the detection of musculoskeletal infection have their shortcomings and limitations. Culture investigation remains the only definitive modality for the identification of the pathogenic organism. However in 7% to 15% of patients with periprosthetic infections, no pathogen can be cultured (16). With the increasing availability of molecular biologic techniques, the surgeon has gained a valuable tool in detecting and differentiating pathogens in orthopaedic infections. The predominant molecular technique available in this capacity is PCR. PCR depends on the activity of the heat-stable Taq polymerase, which through repeated sequences of DNA replication, can tremendously amplify even minute samples of bacterial DNA.

Using RNA probes created to specifically recognize DNA sequences in bacteria, it is now possible to identify a pathogen based solely on its DNA. In patients with suspected infection, this molecular technique can be used to prove infection and provide the likely organism when all other diagnostic modalities have failed. In addition to PCR, other molecular techniques under investigation include ligase chain reaction, reverse transcriptase PCR, branched-chain DNA reaction, monoclonal antibodies directed against unique bacterial proteins, direct detection of target RNA through Northern blotting, in situ hybridization of RNA with labeled complementary DNA sequences, Southern blotting of DNA, and Western blotting of proteins.

The most immediate diagnostic tests that can be performed on samples are a Gram stain or intraoperative frozen section (9). Gram stains allow for quick determination of gram-positive or gram-negative bacteria, as well as their morphology. Gram stains help select early appropriate broad-spectrum antibiotic therapy. More specific antibiotics can be used when sensitivity results have returned.

Feldman et al. (13) investigated the predictive value of intraoperative frozen sections in detecting infection in patients undergoing revision total joint arthroplasty. Infection was defined as five polymorphonuclear cells per high-power field in at least five distinct microscopic fields. Their investigation showed a 100% sensitivity, with all patients found to have positive intraoperative cultures also having positive frozen sections. In addition, their investigation showed a specificity of 96%.

Several types of media are available for culturing bacteria and fungi. Culture the initial specimens taken for aerobic, facultative anaerobic, and obligate anaerobic bacteria. If these specimens fail to yield any growth or there is little response from the patient to antibiotic intervention, other cultures may be considered to detect unexpected infectious agents such as mycobacteria and fungi.

Once these bacteria have been cultured, test for their antibiotic susceptibility. Testing may include the use of in vitro methods, testing for the patients' serum bactericidal activity while on antibiotic therapy, and direct measurement of serum antibiotic levels. In vitro methods include serial dilutions of antibiotic and antibiotic disc diffusion. These tests attempt to determine the concentration of antibiotic necessary to inhibit further growth of bacteria on an agar gel medium or in broth.

The serial dilution method tests multiple concentrations of antibiotic incubated with bacteria attempting to determine the concentration at which the growth of bacteria is halted. This concentration is termed the minimum inhibitory concentration (MIC). If bacterial growth is stopped by serum levels of an antibiotic when given in normal dosages and routes, the bacteria are said to be sensitive. After determination of the MIC, the minimal bactericidal concentration (MBC) can be determined, reflecting the lowest concentration of antibiotic at which 99.9% of all bacteria are killed. Ideally, an antibiotic will have an MIC that is equal to the MBC—that is, the antibiotic most effective in eradicating the pathogen will have the lowest toxicity (28).

Alternatively, the disc diffusion method uses antibiotic-impregnated discs placed in the broth or agar gel medium to determine the susceptibility of bacteria. By measuring the zone of inhibited bacterial growth, the MIC may be determined when compared with a standardized reference. The results of this test are reported as susceptible, intermediate, or resistant, depending on the size of the inhibited growth zones (28).

The patient's own serum can also be used in determining the effectiveness of the chemotherapeutic treatment. Samples of the patient's serum at peak and trough antibiotic levels are used. Peak serum titers of greater than 1:8 have been associated with good outcomes in the resolution of infection.

Use direct measurement of antibiotic levels in the patient's blood to assist in determining whether the levels are within the reference range for effectiveness, as well as in below levels.

**MOLECULAR INVESTIGATION**

**B-LACTAM ANTIBIOTICS**

The b-lactam antibiotics are the most commonly prescribed agents in the treatment of infections of bones, joints, and soft tissue. Included in this class are the penicillins, cephalosporins, carbapenems, and monobactams. Penicillins consist of a thiazolidine ring coupled with a b-lactam ring, to which is attached a side chain. The nucleus of this molecule is the chief structural requirement for biologic activity, and any chemical or metabolic alteration of this portion causes a loss of all significant antibacterial activity. The side chain determines many of the antibacterial and pharmacologic characteristics of the particular penicillin.

Penicillins

Penicillins are bactericidal and act by inhibiting bacterial cell wall synthesis (Fig. 132.1). These cell walls are composed of murein (peptidoglycan) and are essential for the normal growth and development of bacteria. Peptidoglycan is a heteropolymeric component of the cell wall that provides rigid mechanical stability by virtue of its highly cross-linked latticework structure. In gram-positive bacteria, the thickness of this cell wall may be as much as 100 molecules, compared with a thickness of only 1 or 2 molecules in gram-negative organisms. Synthesis involves an N-acetylglucosamine-N-acetylmuramic acid (GlcNAc-MurNAc) disaccharide unit that is attached to a bactoprenyl lipid carrier molecule in the cytoplasmic membrane. Autolytic enzymes open sites in the existing cell wall where the new disaccharide units will be placed.

![Figure 132.1. Location of antibiotic activity in bacterial cell.](image-url)

Once these molecules are donated by the lipid carrier and oriented, transpeptidase enzymes cross-link the peptide of the new GlcNAc-MurNAc moiety with that of another. The key targets of the penicillins in this process are the transpeptidases. By binding tightly to the active site of these enzymes, they inhibit the cross-linking of the cell wall components and reduce the overall tensile strength these cells need to resist osmotic lysis.

The enzymes that bind to penicillins are collectively referred to as penicillin-binding proteins (PBP), because their initial identification was based on their ability to bind with more complex and varied forms of penicillin. The PBP are a diverse group of transpeptidases and carboxypeptidases that are involved in various aspect of cell wall synthesis, and as such, each b-lactam antibiotic may have different affinities for selected PBP. Once the formation of the bacterial cell wall is inhibited, two normally expressed classes of autolysins seem to be responsible for the cidal action of b-lactam antibiotics.

The natural penicillins, penicillin G (benzylpenicillin) and penicillin V (the phenoxymethyl derivative), are very similar in their antimicrobial spectrum for aerobic
gram-positive organisms (Table 132.4 and Table 132.5). They remain the agents of choice in gonococcal and streptococcal arthritis and soft-tissue infections. Penicillin G is five to 10 times more active than penicillin V against gonococcal sensitive to penicillin. The sole virtue of penicillin V in comparison to penicillin G is its stability in an acid environment. Therefore, it is better suited for absorption from the gastrointestinal tract. On an equivalent oral dose, penicillin V may yield plasma concentrations two to five times greater than those provided by penicillin G. Once absorbed, both penicillin G and penicillin V are widely distributed in the body and excreted by the kidneys.

Intramuscular injection of penicillin G yields peak plasma concentrations within 15 to 30 minutes, but this value declines rapidly because of its short half-life (30 minutes). Many attempts have been made to maintain the concentration of penicillin G doses given parenterally. Probenecid has been found to block renal tubule secretion of penicillin, but it is rarely used in this capacity. Instead, repository preparations of penicillin may be used, the two favored compounds being procaine penicillin G and benzathine penicillin G. These preparations allow for slow release of antibiotic from the site of injection, while maintaining bactericidal blood concentrations over an extended period of time.

Newer penicillins grew from discoveries regarding the medium in which Penicillium mold was grown, and the realization that changing the side chain moiety could yield a wide variety of new properties. Investigators soon found a highly reactive precursor of penicillin, 6-aminopenicillanic acid, could be obtained by treating penicillin with an amidase. At that point, an almost infinite number of synthetically generated organic acids could then be fused with 6-aminopenicillanic acid to produce the semisynthetic penicillins.

Three major goals propelled the development of novel penicillin antibiotics. First, there was the need for a more acid-stable penicillin that was orally available. Second, penicillin G and V were effective against gram-positive aerobes but effective only against a handful of gram-negative bacteria. Finally, the issue of penicillin-resistant strains of bacteria had already begun to become a matter of great concern.

The semisynthetic aminopenicillins (ampicillin, amoxicillin, and bacampicillin) were developed to extend the spectrum. These antibiotics are effective against many gram-negative bacteria but are only about one-half as effective against gram-positive bacteria as is penicillin G. Their amino group allows them to traverse the charged outer membrane of gram-negative bacteria easily and reach bactericidal concentrations. They are also acid stable and readily bioavailable through oral dosing. Their main limitation is that they are readily hydrolyzed by β-lactamase enzymes and are not effective against P. aeruginosa. The aminopenicillins are effective against non-β-lactamase—producing strains of E. coli, H. influenzae, Proteus, Salmonella, and Shigella.

The carboxypenicillins, ureidopenicillins, and piperazinc penicillins were all developed to treat infections of P. aeruginosa. The carboxyopenicillins carbencillin and ticarcillin were the first antipseudomonal agents developed. They are ineffective against gram-positive organisms but have excellent activity against enteric rods and Pseudomonas. Piperazine penicillins, such as piperacillin, and the ureidopenicillins, such as mezlocillin and azlocillin, are even more effective against enteric bacteria and Pseudomonas, as a result of their high affinity for gram-negative PBPs. Unfortunately, all of the antipseudomonal penicillins are sensitive to β-lactamase, are generally more toxic than their predecessors, and must be provided parenterally.

Bacterial resistance to penicillins can be mediated through a variety of means: Chromosomal changes in the affinity of PBPs for penicillin, reduced antibiotic uptake, and decreased activities of bacterial autolysins are all possible mechanisms. The most commonly encountered resistance to penicillins, however, is based on the enzymatic destruction and inactivation of the β-lactam ring. Different microorganisms elaborate a number of distinct β-lactamas, although most bacteria are capable of producing only one form of the enzyme. The substrate specificities of these enzymes are relatively narrow, and they can often be described as either penicillinases or cephalosporinases. Other “broad-spectrum” enzymes may also be found that are capable of hydrolyzing a variety of β-lactam antibiotics.

In general, gram-positive bacteria produce large amounts of β-lactamase, secreting it extracellularly. In staphylococcus, the information for penicillins is encoded on a plasmid that can be readily transferred by bacteriophage to other bacteria. Different microorganisms elaborate a number of distinct β-lactamas, although most bacteria are capable of producing only one form of the enzyme. The substrate specificities of these enzymes are relatively narrow, and they can often be described as either penicillinases or cephalosporinases. Other “broad-spectrum” enzymes may also be found that are capable of hydrolyzing a variety of β-lactam antibiotics.

The semisynthetic β-lactamases include methicillin, nafcillin, and the oxazolyl penicillins (oxacillin, cloxacillin, and dicloxacillin). These penicillins are more toxic and have less activity than penicillin G against gram-positive cocci, but it is their ability to resist hydrolysis by the β-lactamases produced by staphylococci that allows them to remain the drug of choice in most staphylococcal disease.

Clinical microbiology laboratories do not typically use the term “methicillin-resistant Staphylococcus.” Most often, the laboratory will test staphylococci with an oxacillin-impregnated disk, reporting the organism as “resistant to oxacillin.” Oxacillin is the commonly used class-disk for all penicillinase-resistant penicillins. Although

Table 132.5. Pathogenic Organism and Selected Treatment Options

In one institution's experience, 12% of outpatient penicillin-resistant strains of E. coli, H. influenzae, Proteus, Salmonella, and Shigella. In the cases of the ampicillin/subactam and amoxicillin/clavulanic acid, the combination has extended the antibiotic spectrum to include β-lactamase—producing strains of Bacteroides fragilis, Enterobacter, E. coli, Haemophilus ducreyi, H.
**Cephalosporins**

The cephalosporins and related cephamycins constitute the largest group of β-lactam antibiotics. The cephalosporins are semisynthetic penicillin derivatives of 7-aminocephalosporanic acid, consisting of a β-lactam ring coupled with a six-membered dihydروthiazine ring (compared with the five-membered ring of penicillins). In contrast to penicillins, cephalosporins can have up to three side chains attached to the nucleus of the molecule. The R1 group is attached to the same site as the R group of penicillin and determines the antibiotic properties of the molecule. The R2 group determines the metabolic and pharmacokinetic properties of the molecule, and the R3 group acts to increase the resistance of cephalosporins to the action of β-lactamase.

The cephalosporins have been divided into three major groups, referred to as generations, depending on their efficacy against gram-negative bacteria. Some of the more recently developed cephalosporins are referred to as “fourth generation,” but this classification has yet to achieve widespread acceptance.

The first-generation cephalosporins are effective primarily against gram-positive bacteria including pneumococci, streptococci, *C. perfringens*, *Corynebacterium diphtheriae*. *S. epidermidis*, and methicillin-sensitive *S. aureus*. The relevant spectrum of activity against gram-negative bacteria for these first-generation cephalosporins is limited to *E. coli*, *Klebsiella*, and *Proteus mirabilis*. It is important to note that most of the orally available cephalosporins are from this first-generation group (17,21,24) (Table 132.6).

Chloramphenicol application rarely causes hypersensitivity reactions or systemic toxicity. Bacitracin is markedly nephrotoxic if absorbed, producing proteinuria, hematuria, and nitrogen retention. Its systemic use has been virtually abandoned.

Clostridium difficile bactoprenyl phosphate is left available to receive to new disaccharide monomeric subunits to be incorporated into the existing murein, halting cell wall synthesis. Bacitracin is another adverse effect of the antibiotic, manifesting mainly as vestibular dysfunction owing to the destruction of hair cells by prolonged drug trough levels in excess of the MIC.

Aminoglycoside antibiotics are associated with nephrotoxicity, and their dosage must be adjusted on the basis of the patient's baseline renal function. Ototoxicity is another adverse reaction to penicillin includes a serum sickness—type reaction that may produce urticaria, pruritis, joint swelling, and respiratory complications up to 2 weeks after the patient has received penicillin. This particular reaction can occur on the patient's first exposure to penicillin. IgG-mediated hemolytic anemia can also occur in some patients, caused by complement-mediated lysis of red blood cells coated with penicillin.

When taking histories, carefully question all patients about reactions to penicillin administration in the past. For those patients with an unclear history who must receive penicillin, penicillin breakdown products are commercially available that can be injected intradermally. A wheal and flare will be seen in those patients with an allergy to penicillin necessitating the use of an alternative antibiotic. In cases in which there is a significant risk of anaphylaxis between penicillin administration and death, patients can be desensitized to penicillin by sequential oral or parenteral administration of small doses over several hours.

About 5% of patients allergic to penicillins are also allergic to cephalosporins. In those patients whose reactions are not mediated by an IgE mechanism, cephalosporins can safely be used, but in those patients with a clear history of IgE-mediated penicillin allergy, cephalosporins are best avoided.

Other evidence of toxicity seen with the use of penicillins includes nausea, vomiting, and diarrhea. These effects are more pronounced with the broad-spectrum penicillins, such as ampicillin and amoxicillin. In cases in which massive doses of penicillin are administered, there can be direct cation toxicity (NH₄⁺, K⁺). Methicillin, nafcillin, and other penicillins have been known to cause granulocytopenia occasionally, especially in children.

Methicillin causes interstitial nephritis more commonly than does nafcillin. The antibiotic binds to the basement membrane of the renal tubules and becomes a target of antibody binding that, in turn, activates complement and transmural capillary elevation in serum and can induce hemostatic defects, leading to bleeding tendencies. Ampicillin frequently causes skin rashes, some of which are not related to allergic reaction.

The cephalosporins cefamandole, moxalactam, cefmetazole, cefotetan, and cefoperazone frequently cause hypoglycemia and bleeding disorders. Administration of vitamin K, 10 mg twice weekly, can prevent such an outcome. Moxalactam can also interfere with platelet function and has induced severe bleeding. Its use has been largely abandoned. Cephalosporins can cause severe disulfiram-like reactions in patients who ingest alcohol or alcohol-containing products.

**Aminoglycoside Antibiotics**

The aminoglycosides include gentamicin, amikacin, tobramycin, and kanamycin. They exert their action by binding to the 30s ribosomal subunit in bacteria, disrupting the conformation of mRNA, and forcing erroneous tRNA binding to the codon. At high concentrations, aminoglycosides can bind to both the ribosomes and mRNA, disrupting protein translation beyond initiation as well as permanently altering the ribosome, rendering it functionally useless.

The aminoglycosides have a broad spectrum but are limited by several factors. First, because they require active protein production in the bacteria to exert their effect, they cannot be used with agents that reversibly interfere with protein synthesis. It is for this reason that aminoglycosides are not bactericidal in the presence of chloramphenicol. Second, the rate of bacterial killing by an aminoglycoside increases with the drug concentration, with the limiting factor being the rate at which the antibiotic enters bacterial cells. Third, aminoglycosides are effective only under aerobic conditions, thus they are ineffective against obligate anaerobic bacteria. Fourth, aminoglycosides are ineffective in areas of high acid or salt concentrations. Fifth, because of their poor penetration into the host cells, they offer little activity against intracellular bacteria. Finally, aminoglycosides are relatively toxic with a limited therapeutic window. High trough levels of aminoglycosides are classically associated with ototoxicity and nephrotoxicity.

The use of aminoglycosides is primarily for aerobic gram-negative rods. By administering aminoglycosides with a β-lactam, the antibiotics work synergistically to reduce the dosage, increase the therapeutic margin, and broaden the spectrum of the aminoglycosides. Through this combination therapy, clinicians can avoid the toxicities associated with this antibiotic.

Resistance to aminoglycosides can be due to two major mechanisms. In order to create sufficient concentrations in bacteria, the aminoglycosides must be transported intracellularly by the aid of a specific carrier protein. Bacteria that generate lower levels or weakly binding transport protein are innately resistant to aminoglycosides. Another mechanism that confers resistance to bacteria is the presence of a number of enzymes that deactivate the antibiotic by means of acetylation, phosphorylation, or adenylation. These chemical modifications do not allow the aminoglycoside molecule to interact with bacterial ribosomes to exert their bactericidal activity.

Aminoglycoside antibiotics are associated with nephrotoxicity, and their dosage must be adjusted on the basis of the patient's baseline renal function. Ototoxicity is another adverse effect of the antibiotic, manifesting mainly as vestibular dysfunction owing to the destruction of hair cells by prolonged drug trough levels in excess of 10 mg/mL. Loss of hearing can occur as well, and it is occasionally extensive and irreversible.

**Bacitracin**

Bacitracin is a cell wall synthesis inhibitor that is fairly toxic when administered systemically. The bactericidal action of bacitracin works by blocking the dephosphorylation of the bacitreprenyl phosphate molecule after it has donated its GlcNac-MurNac disaccharide to the growing peptidoglycan chain. As a result, no bacitreprenyl phosphate is left available to receive new disaccharide monomeric subunits to be incorporated into the existing murein, halting cell wall synthesis.

Bacitracin is an extremely toxic compound when administered parenterally, and therefore, it is restricted to topical and oral use. It can be found in topical creams for use in treating eye and skin infections caused by staphylococci and streptococci, as well as oral preparations for the treatment of pseudomembranous colitis caused by Clostridium difficile. Its use in this capacity is possible because of its poor absorption from oral intake.

Bacitracin is markedly nephrotoxic if absorbed, producing proteinuria, hematuria, and nitrogen retention. Its systemic use has been virtually abandoned. Topical application rarely causes hypersensitivity reactions or systemic toxicity.

**Chloramphenicol**
Chloramphenicol is a bacteriostatic antibiotic that interferes with the action of peptidyl transferase, inhibiting the formation of a peptide bond and arresting peptide chain elongation. Because of its bacteriostatic nature, it is generally not administered in combination with a bactericidal antibiotic. Chloramphenicol's ability to penetrate host cells is at the same time a great advantage and a drawback. Its accumulation in the host cell's cytoplasm allows the antibiotic to be used against intracellular organisms. At the same time, these cytoplasmic concentrations interfere with ribosomal protein synthesis, depressing bone marrow activity and causing a pancytopenia.

In infants, ineffective hepatic clearance of the medication leads to toxic levels, and leads to the condition known as gray-baby syndrome, with vomiting, flaccidity, hypothermia, gray color, shock, and collapse. One idiosyncratic reaction to the medication is the development of an aplastic anemia. It is not related to dosage or length of use, but the odds of developing this condition are increased by extended use of the medication. It is for these reasons that clinicians in the United States have limited its use.

The antibiotic remains an effective treatment for infections caused by *H. influenzae* and *Rickettsia* sp. Resistance to chloramphenicol is mostly limited to enteric bacteria. Three modes of resistance have been described in these organisms. The mechanism most commonly found is a gene coding for an enzyme that is able to acetylate both chloramphenicol and tetracyclines, thereby inactivating them. The second method of resistance involves the ability of certain bacteria to limit their permeability to the antibiotic. The final resistance factor discovered is a mutation in the 50s subunit of the bacterial ribosome that results in poor recognition of the antibiotic by its target (35).

Other adverse reactions to chloramphenicol include GI upset with nausea, vomiting, and diarrhea. Chloramphenicol may also prolong the half-lives of many drugs including phenytoin, tolbutamide, chlorpropamide, and warfarin. This effect is attributed to the inhibition of liver microsomal enzymes by the antibiotic.

**Fluoroquinolones**

The fluoroquinolones are a group of synthetic quinolones developed with broad-spectrum effectiveness against most gram-negative and some gram-positive bacteria. Their proposed mechanism of action is through binding to the a-subunit of bacterial DNA gyrase (topoisomerase II), inhibiting the process of DNA supercoiling, a necessary step in the replication of DNA. The fluoroquinolones can be used to treat infections in most parts of the body including the urinary tract and to treat gonorrhea, bacterial diarrhea, and infections of the skin, bones, and joints as well. They are generally effective against *N. gonorrhoeae* and *S. aureus*, and they are usually effective against *P. aeruginosa*.

The most prominent adverse effects of the fluoroquinolones are nausea, vomiting, and diarrhea. Occasionally, headache, dizziness, insomnia, abnormal liver function tests, or skin rash may develop. Concomitant administration of theophylline and fluoroquinolones can lead to elevation of theophylline levels with increased risk of toxic effects, especially seizures (Table 132.9). Fluoroquinolones have been shown in animal models to damage immature cartilage, but no study has documented this finding in the human pediatric population.

**Glycopeptide Antibiotics**

The glycopeptide antibiotics vancomycin and teicoplanin have become extremely important tools against methicillin-resistant staphylococci. These antibiotics are macromolecules, consisting of seven amino acids at their core, with all glycopeptides sharing a homology of five of these amino acids. Because of their size, the glycopeptide antibiotics cannot effectively penetrate the outer membrane of the gram-negative bacteria and therefore can have no effect on these organisms. Their inability to penetrate the cytoplasmic membrane of gram-positive bacteria restricts their activities to the metabolic processes of the microbe occurring outside this membrane.

Each glycopeptide antibiotic possesses a ring-like configuration, with a central cleft binding tightly to its target. The active sites of vancomycin and teicoplanin have been shown to recognize tripeptides with a stereochromical configuration of L-D-D. This configuration can be found only within the MurNAc pentapeptide, where an L-amino acid can be found at position 3 with two terminal D-alanines. When vancomycin is administered to susceptible gram-positive bacteria, it first attaches to all available L-D-D residues in the cell wall.

Once these sites are saturated, the glycopeptide antibiotic attaches to the L-D-D of GlcNAc-MurNAc moieties that are attached to the bactoprenyl transferring lipid. Once in this position, the glycopeptide acts as a steric hindrance, blocking peptidoglycan transglycosidase from transferring the disaccharide unit to the peptidoglycan growth point. Moreover, the attachment of vancomycin to the acyl-D-alanine-D-alanine of non-cross-linked dipeptides already incorporated in the cell wall interferes with their ability to be cross-linked.

Vancomycin and teicoplanin are used to treat severe infections caused by *C. difficile*, multiply resistant *S. aureus*, coagulase-negative staphylococci, and penicillinase-producing strains of *S. pneumoniae* and *S. pyogenes*. A glycopeptide antibiotic can also be used in combination with an aminoglycoside to treat infections caused by highly resistant *E. faecalis*.

Adverse reactions are rare with vancomycin use. Although the use of vancomycin has occasionally been associated with ototoxicity and nephrotoxicity, the highly purified preparations of vancomycin that are now commercially available are generally considered safe for most patients and make these toxicities mild. Vancomycin is an irritant to tissue, and patients may develop phlebitis at the site of injection as well as a nonimmune-mediated histamine release referred to as the "red man syndrome." This reaction can largely be prevented by the administration of an antihistamine and slow infusion. Vancomycin is excreted through the kidneys, and in patients with altered renal function, peak and trough blood levels of the antibiotic should be checked to avoid any of the previously mentioned toxicities.

Resistance to glycopeptide antibiotics has been found mainly among *Enterococcus* sp primarily owing to the production of a membrane-bound protein known as VanA. VanA is a D-alanine-D-alanine ligase that synthesizes other mixed dipeptides, replacing the D-alanine-D-alanine within MurNAc. These VanA-containing enterococci no longer express the L-D-D target for the binding of glycopeptide antibiotics and are therefore rendered resistant to its actions. VanA has been found to be transferred to other bacteria via conjugation. Less commonly, *Enterococcus* sp express VanB or VanC proteins whose modes of action are most likely similar to that of VanA but have not been found to be transferred by conjugation (17,21-35-37-57-59).

**Lincosamide Antibiotics**

The Lincosamides include the antibiotics clindamycin and lincomycin. The difference between these two antibiotics is the presence at position 7 of a chlorine group on clindamycin that is a hydroxyl group on lincomycin. This difference allows clindamycin to be more easily absorbed orally and more active against anaerobic bacteria. The Lincosamides have the same receptor on the 50s subunit of the bacterial ribosome as chloramphenicol. Lincosamides, however, are able to cause a more rapid dissociation of the ribosome into its constituent 50s and 30s subunits.

The spectrum of action for clindamycin is similar to that of penicillin G and erythromycin, but it is used primarily in the treatment of infections caused by the strict anaerobe *B. fragilis*, especially in patients with known reactions to penicillin. It is sometimes used to treat abscesses or sepsis caused by other Bacteroides sp, *Actinobacillus*, *Actinomyces*, *Capnocytophaga*, *Clostridium*, *Flavobacterium*, *Fusobacterium*, or *Peptostreptococcus*. Most of these bacteria are anaerobic or...
Sulfonamides can cause a wide variety of untoward effects owing partly to allergy and partly to direct effects. The most common adverse effects include fever, skin reactions, and blood disorders. Resistance to clindamycin is seen in organisms that also exhibit resistance to macrolide antibiotic. The resistance appears linked to the same mechanisms that alter the bacterial 50s ribosomal subunit and produce resistance to the macrolides (17,35).

**Macrolide Antibiotics**

Macrolide antibiotics are large, cyclic molecules that contain a lactone ring. Until recently, erythromycin was the only macrolide antibiotic available. The increasing incidence of resistant strains has led to the development of the newer macrolides azithromycin and clarithromycin. These antibiotics are bacteriostatic at low concentrations and bactericidal at high concentration. Macrolides bind to ribosomes, allowing the initiation and formation of a short peptide sequence, but inhibit the process of translocation and elongation soon thereafter. This blocked complex becomes unstable, and eventually the ribosomal fragments are released from the mRNA strand.

The popularity of the macrolides is based on their spectrum of action similar to that of penicillin G, resistance to β-lactamase, oral availability, and absence of major toxicity. Most adverse reactions are related to disturbances of the gastrointestinal tract. Erythromycin is used in treating Legionnaires' disease, diptheria, pertussis, and atypical pneumonia cause by Mycoplasma or Chlamydia. The newer macrolides have broadened the spectrum of this class of antibiotics. Azithromycin has also been shown to be effective against *Borrelija burgdorferi*, the causative agent of Lyme disease; *H. influenzae*, and *Toxoplasma gondii*. Clarithromycin is unusual in its effectiveness against *Mycobacterium avium-intracellulare* and several of the atypical mycobacteria.

Resistance to macrolides is conferred by the 50s ribosomal subunit in the bacteria resulting in an inability of these subunits to recognize the antibiotic (35).

Adverse effects of macrolide antibiotics given orally include anorexia, nausea, vomiting, and diarrhea. Erythromycin can also produce acute cholestatic hepatitis (fever, jaundice, impaired liver function), probably as a hypersensitivity reaction. Other allergic reactions include fever, eosinophilia, and rashes. Erythromycins can also inhibit cytochrome P450 and increase the effects of anticoagulants, digoxin, cyclosporine, and antihistamines.

**Polymyxins**

Polymyxin antibiotics are large polypeptide antibiotics that contain fatty acids, multiple positive charges, and a long alkyl side chain. These properties allow polymyxins to act as cationic detergents, binding avidly to lipopolysaccharide and phospholipidethanolamines in gram-negative outer membranes but poorly to phosphatidylcholine, a constituent of human cell membranes. Therefore, polymyxins are effective against gram-negative bacteria.

Two polymyxins are available in the United States, polymyxin B and polymyxin E. Because of their toxicity, polymyxins are not the drug of choice in the treatment of any bacterial infection. Instead they can be used as a second-line drug to treat severe or life-threatening infections caused by *P. aeruginosa* or other gram-negative rods when such infections have not responded to standard therapies.

Local reactions and hypersensitivity to topical administration are rare. Systemic levels of polymyxins can cause paresthesias, dizziness, and lack of coordination, which disappear when the drug has been excreted. Very high blood levels (greater than 30 mg/ml) can cause respiratory paralysis. Polymyxins may also cause proteinuria and hematuria.

**Rifampin**

Rifampin is a transcripational inhibitor that binds to the β-subunit of DNA-dependent RNA polymerase in bacteria. It allows the creation of the first phosphodiesterase bond to form in the RNA but then blocks any subsequent bond formation, and effectively terminates initiation in RNA synthesis. Resistance to rifampin is based on a mutation of the gene coding for the β-subunit of the bacterial DNA-dependent RNA polymerase that will not allow for proper binding of rifampin. Because of the high rate of spontaneous mutations that create resistance to rifampin, its use has been limited to (1) long-term treatment of tuberculosis and leprosy, (2) prophylaxis for those exposed to patients with meningitis due to *H. influenzae* type b or *N. meningitidis*, and (3) combination therapy with vancomycin, nafcillin, and ciprofloxacin in the treatment of endocarditis or osteomyelitis caused by *S. aureus* or *S. epidermidis*.

Rifampin imparts a harmless orange color to urine, sweat, tears, and contact lenses of which patients should be warned. Occasional adverse reactions include rashes, thrombocytopenia, nephritis, and impairment of liver function. Rifampin induces the cytochrome P450 system of the liver and increases the elimination of anticoagulants and contraceptives. Likewise, administration of rifampin with ketocazoloe, cyclosporin, or chloramphenical results in significantly lower serum levels of these medications.

**Tetracyclines**

Tetracyclines are broad-spectrum bacteriostatic agents that are capable of penetrating well into host cells. They are most effective against rapidly multiplying bacteria. This group of antibiotics include tetracycline, doxycycline, demeclocycline, and minocycline. The tetracyclines exert their action by binding to the 30s bacterial ribosomal subunit and inhibiting the correct positioning of the incoming tRNA, thereby inhibiting peptide elongation. The earlier tetracyclines were not well absorbed from the intestinal tract and, as a result tilled much of the normal flora, resulting in colitis. However, with the development of the more lipophilic semisynthetic tetracyclines doxycycline and minocycline, intestinal absorption has increased and reduced the incidence of colitis.

Nausea, vomiting, and diarrhea are the most common reasons for discontinuing tetracycline. These symptoms can usually be controlled by administering the antibiotic with food. Use in children under the age of 12 can impair bone development and stunt development of teeth. Tetracyclines can probably impair hepatic function and may also result in liver necrosis, especially in small children. Renal tubular acidosis and other renal injuries resulting in nitrogen retention have been attributed to the administration of outdated tetracycline preparations. Intravenous injection of tetracycline can lead to venous thrombosis, whereas intramuscular injection produces painful local irritation and should be avoided. Administration of systemic tetracycline, especially demeclocycline, can induce sensitivity to sunlight or ultraviolet light, particularly in fair-skinned individuals. Dizziness, vertigo, nausea, and vomiting have been particularly noted in patients receiving minocycline.

Tetracyclines are used primarily in the treatment of infections caused by intracellular organisms such as *Chlamydia, Rickettsia*, and pneumonia caused by *M. pneumoniae*. Resistance to tetracyclines is based on a plasmid-encoded active efflux system. Although tetracycline entry into the cell is not altered, an active system for pumping the antibiotic out of the bacteria is established (35).

**Metronidazole**

Metronidazole is a nitroimidazole antiprotozoal drug that also has striking bactericidal effects against most anaerobes, including Bacteroides and clostridia. It exerts its antibacterial effect through the formation of short-lived, highly cytotoxic intermediates that develop in anaerobic conditions. It is well absorbed when taken orally, and may accumulate in patients with hepatic insufficiency. Metronidazole is considered for use in anaerobic and protozoal infections, and antibiotic-associated colitis. Adverse effects of the medication include nausea, diarrhea, stomatitis, and peripheral neuropathy with prolonged use. Advise patients to avoid alcohol ingestion because of metronidazole's disulfiram-like effect.

**Trimethoprim-Sulfamethoxazole**

Trimethoprim and sulfamethoxazole (TMP/SMX) act at different points in the chemical pathway that produces dihydrofolic acid for bacterial cells. Dihydrofolic acid acts as a reducing agent in bacteria and is necessary for normal cellular processes. Because of their actions on the same pathway, TMP/SMX act synergistically against susceptible bacteria as well as some parasites. Resistance to TMP/SMX develops when enzymes in the dihydrofolic acid pathway mutate and no longer bind these medications as avidly. Because of the use of two medications on the same chemical pathway, however, the development of resistant strains is somewhat hampered (35).

Sulfonamides can cause a variety of untoward effects owing partly to allergy and partly to direct effects. The most common adverse effects include fever, skin
rashes, photosensitivity, urticaria, nausea, vomiting, and diarrhea. Other effects include stomatitis, conjunctivitis, arthritis, hepatitis, exfoliative dermatitis, polyarteritis nodosa, Stevens-Johnson syndrome, and psychosis. Sulfonamides can produce anemia (hemolytic or aplastic), granulocytopenia, thrombocytopenia, or leukemoid reactions. These are rare except in certain high-risk patients. Sulfonamides cause hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency, and sulfonamides taken near the end of pregnancy increase the risk of kernicterus in the newborn infant.

Trimetrexoprim produces the predictable adverse effects of an antifolate drug, especially megaloblastic anemia, leukopenia, and granulocytopenia. These effects can be prevented by the simultaneous administration of folic acid.

**DRUGS EFFECTIVE AGAINST MYCOBACTERIA**

**Isoniazid**

Isoniazid (INH) is a bactericidal antibiotic that interferes with the synthesis of mycolic acid, an essential component of the cell wall complex of *Mycobacterium tuberculosis*. When used as prophylaxis for tuberculosis, it can be given as monotherapy. With the rise of multidrug-resistant TB, however, INH must be given in combination with other antitubercular drugs. Another antitubercular drug ethionamide is closely related to INH and has the same mode of action.

The most common side effects of INH use, seen in 10% to 20% percent of patients, are on the peripheral nervous system and CNS. These are related to a relative pyridoxine deficiency and include peripheral neuritis, insomnia, restlessness, muscle twitching, urinary retention, and even convulsions or psychotic episodes. Most of these complications can be avoided by the administration of pyridoxine (vitamin B6). Isoniazid has been associated with hepatotoxicity with abnormal liver function tests, clinical jaundice, and multilobular necrosis.

**Pyrazinamide**

Pyrazinamide is a relative of nicotinamide and strongly inhibits the growth of tubercle bacilli and other mycobacteria. Pyrazinamide is well absorbed from the gastrointestinal tract and widely distributed throughout the body. Tubercle bacilli develop resistance to pyrazinamide fairly readily, but there is no cross-resistance with INH or other antitubercular drugs. The major adverse effects of pyrazinamide include hepatotoxicity (in 1% to 5% of patients), nausea, vomiting, drug fever, and hyperuricemia.

**Rifampin**

The use of rifampin for bacterial infections has been discussed earlier. It is also used as a front-line chemotherapeutic agent against mycobacterial infections.

**Ethambutol**

Ethambutol is a bactericidal antibiotic that inhibits the synthesis of cellular metabolites by an unknown mechanism. In combination with other medication, it is used in the short-term treatment of tuberculosis. Ethambutol may cause reduced visual acuity, optic neuritis, and perhaps retinal damage in about 0.8% of patients but rarely in patients with normal renal function.

**Cycloserine**

Cycloserine acts as an analog of D-alanine-D-alanine, and inhibits the formation of peptidoglycan cross-links by acting as a competitive inhibitor of the transpeptidase enzymes. Cycloserine is indicated primarily as a second-line agent in the treatment of tuberculosis. Its use has been associated with convulsions, other serious CNS dysfunction, and psychotic reactions.

**Streptomycin**

Streptomycin is identical in action to the aminoglycosides previously discussed and possesses the same adverse effects. Most tubercle bacilli are inhibited by streptomycin, but the drug can exert its effects only on extracellular bacteria because only 10% of the antibiotic can penetrate cells that harbor the intracellular pathogen.

**Dapsone**

Dapsone is a sulfone antibiotic with an identical mode of action and adverse effects as the sulfonamides. For many years, dapsone was the treatment of choice against *Mycobacterium leprae*. With the rise of dapsone resistance among leprosy bacilli during the past few years, standard treatment of leprosy now combines dapsone with other antitubercular drugs.

**DRUGS EFFECTIVE AGAINST FUNGI**

Because of the eukaryotic nature of fungi, the problem of developing a selectively toxic antifungal agent has been difficult. It has been solved by the use of agents that inhibit the synthesis of unique fungal cell wall or membrane. Thus, most antifungal agents act by binding or inhibiting the synthesis of ergosterol, a steroid found only in fungal cell membranes. In high concentrations, however, these antibiotics can have toxic effects on human cells as well, making the treatment of systemic fungal disease difficult.

**Polyene Antibiotics**

Amphotericin B and nystatin are polyene antibiotics. They are selectively toxic to fungi because of their ability to preferentially bind ergosterol. This binding disorganizes the lipid bilayer, and fungal metabolites leak out of the damaged cell. In addition to their ability to bind ergosterol, the polyenes can bind to cholesterol in the human cell membrane. It is for this reason that amphotericin B is toxic when used IV, and high-dose therapy may damage renal basement membranes. This is not a problem with nystatin, because it is not given intravenously. Regardless of its toxic effects, amphotericin remains the drug of choice in the treatment of systemic aspergillosis, blastomycosis, candidiasis, coccidiomycosis, cryptococcosis, histoplasmosis, mucormycosis, and sporotrichosis. Nystatin is used in the treatment of cutaneous and mucocutaneous Candida infections. Because nystatin is not absorbed well from the gut, it is often used in the treatment of gastrointestinal candidiasis.

Intravenous injection of amphotericin B usually produces chills, fever, vomiting, and headache. The severity of these reactions may be diminished by reducing the dosage temporarily, administering aspirin, phenothiazines, antihistamines, or corticosteroids; or stopping injections for several days. Therapeutically active amounts of amphotericin B commonly impair renal and hepatocellular function, and produce anemia.

**Azole Antibiotics**

The azole antibiotics are fungistic and exert their antifungal effect by blocking the synthesis of ergosterol through the inhibition of the cytochrome P-450 enzyme lanosterol-14-demethylase. When the available ergosterol for cell growth is depleted and there is no additional supply of ergosterol produced, fungal growth ceases.

The azole antifungals can be used topically in the treatment of dermatophyte infections, chronic mucocutaneous candidiasis, candidiasis in immunodepressed individuals, chromoblastomycosis, paracoccidioidomycosis, and cutaneous or lymphatic sporotrichosis.

Adverse effects of the azole antifungal drugs include vomiting, nausea, diarrhea, rashes, and sometimes impairment of hepatic function. Fluconazole and ketoconazole inhibit cytochrome P450 and may increase serum concentrations of phenytoin, cyclosporine, oral hypoglycemic drugs, and anticoagulants.

**Nucleoside Analogs**

Flucytosine is the only nucleoside analog used in the treatment of fungal infections. In fungal cells, flucytosine is enzymatically converted to fluorouracil, and acts to terminate RNA replication, and thus protein synthesis. Flucytosine can be used as a single agent to treat Candida infections of the urinary tract, and is used in combination with amphotericin B in the treatment of systemic candidiasis or cryptococcosis. As much as 15% of fungal isolates, however, rapidly develop resistance to flucytosine when it is used as a single agent. In addition, flucytosine may be toxic in some patients, with prolonged serum levels causing bone marrow depression with
leukopenia or thrombocytopenia, hair loss, and abnormal liver function.

**Griseofulvin**

Griseofulvin is a fungistatic antibiotic produced by Penicillium and is used to treat dermatophyte infections that are not responsive to topical antibiotics. It may also be administered orally to eradicate infections that are localized in the stratum corneum. It is believed that griseofulvin acts as a colchicine-like agent, interfering with cellular microtubule assembly and inhibiting fungal mitosis. Although griseofulvin is effective against dermatophytes, it has limited effectiveness for the treatment of tinea versicolor or tinea nigra. It is well tolerated, with headache being the most commonly reported adverse reaction.

**Allylamine Antibiotics**

Naftifine and terbinafine are two members of the newer allylamine class of antifungal agents available. They are used mostly to treat dermatophyte infections, such as athlete's foot and ringworm. These antibiotics are fungicidal and work through allosteric inhibition of squalene epoxidase, leading to an accumulation of high levels of squalene and inhibition of ergosterol synthesis (39).

**STREPTOGRAMIN ANTIBIOTICS**

The streptogramin antibiotics are members of the macrolide-lincosamide-streptogramin family and function to inhibit protein synthesis by interfering with bacterial ribosomal function. Pristinamycin is a naturally occurring antibiotic whose existence has been known for several years. The novel antibiotic Synercid is composed of two synthetic derivatives of pristinamycin, quinupristin, and dallopristin mixed in a 30:70 ratio, respectively. Either component used alone has a bacteriostatic effect, but when they are combined, the antibiotic is a powerful bactericidal agent. Consequently, quinupristin/dalfopristin has improved activity against pathogens resistant to macrolides and lincosamides. In addition, quinupristin/dalfopristin is also active against pathogens resistant to β-lactams and glycopeptide antibiotics owing to its differences in chemical structure and mode of action. This and other novel antibiotics in development will be important against emerging strains of resistant bacteria in the future (14,17,39).

**PROLONGED ANTIBIOTIC USE**

Infections of the bone and joints, because of their severity and in many instances the relative lack of blood supply, may require high doses of antibiotic over prolonged periods of time. This antibiotic therapy may begin in the operating room but will need to continue throughout the patient's stay at the hospital and while at home. With the introduction of the Hickman, Brovici, and PICC types of indwelling catheters, one of the obstacles to home antibiotic therapy has been conquered. In addition, the training of visiting home nurses to educate patients and supervise the infusion of antibiotics, as well as the efforts of pharmaceutical services to provide adequate resources, has made this goal of long-term therapy far more achievable (14).

Some problems that are unique to the use of long-term antibiotic remain, however. For those antibiotics with known toxicities, such as the aminoglycosides or vancomycin, blood-level monitoring is necessary to avoid toxic side effects. Audiology testing is needed for a baseline before beginning therapy and may be needed at some point during the course of treatment to avoid vestibular and cochlear damage. Other forms of antibiotics may require serial complete blood counts and liver function tests to avoid toxicity. As mentioned earlier, serum bactericidal concentrations (SBC) can be measured to ensure that the antibiotic concentrations remain within the therapeutic range. In many instances, the SBC can be measured to ensure that the antibiotic concentrations remain within the therapeutic range.

Ostermann PAW, Seligson D, Henry SL. Local Antibiotic Therapy for Severe Open Fractures: A Review of 1085 Consecutive Cases.

The portals of entry for osteomyelitis, or inflammation of the bone, can result from hematogenous seeding, from direct inoculation (i.e., following open fractures or open reduction and internal fixation of fractures), or from the contiguous spread of bacteria from infected structures. Early diagnosis and effective surgical and antibiotic management can control the infection; suppression of infection may last a lifetime.

Since the early 1980s, limb salvage with good functional outcome has been enhanced by the addition of microvascular and local muscle transfers, bone grafting techniques, bone transport for large bone defects, newer antibiotics, and local antibiotic delivery systems. The treatment of osteomyelitis requires the work of a team, consisting of the orthopaedic surgeon, an infectious disease physician, and, in complex cases involving soft-tissue defects or inadequate soft-tissue coverage, a plastic surgeon. In many institutions, some orthopaedic nurses are specially trained in the care of patients with orthopaedic infections.

### PATHOGENS

The organisms that cause osteomyelitis vary depending on the portal of entry and the type, age, and associated medical conditions of the host. Unfortunately, it is usually not possible to accurately predict the specific pathogen on the basis of clinical presentation alone. In the past, the most common causes of osteomyelitis were *Staphylococcus aureus* and various streptococcal species. Gustilo et al. (22) and Patzkas et al. (48) reported that *S. aureus* and coagulase-negative staphylococci were the most common organisms causing infections in open fractures. However, the microbiology of musculoskeletal sepsis has been changing in recent years. While *S. aureus* remains the predominant cause of osteomyelitis, there has been an increase in the frequency of infections caused by gram-negative organisms (52, 53). The portal of entry is an important consideration in the determination of the microbiology. Hematogenous osteomyelitis is most commonly caused by *S. aureus*. In the past, *Haemophilus influenzae* type B (HiB) was a common organism in children, but the advent of HiB vaccine has made it a rare cause (3). Causes of osteomyelitis due to direct inoculation, such as into an open fracture, will be influenced by the environment in which the injury occurred. For example, injuries occurring in water may lead to infection with *Aeromonas or Plesiomonas*.

Nail puncture wounds of the foot, particularly through a tennis shoe, are associated with infection with *Pseudomonas aeruginosa* (28, 50).

Underlying medical conditions of the host also influence the expected microbiology. Intravenous drug users may have *P. aeruginosa* and other gram-negative bacilli as causes of their osteomyelitis (18, 39, 61). Patients with sickle cell disease are prone to the development of Salmonella osteomyelitis. Osteomyelitis caused by fungal infections is more likely to be seen in immunocompromised hosts. Diabetic foot infections leading to osteomyelitis often are polymicrobial, often involving anaerobes and gram-positive and gram-negative aerobic bacilli. Patients infected with the human immunodeficiency virus (HIV) are at risk for a variety of unusual infections, including atypical mycobacteria.

One of the greatest problems for the future is the growing frequency of antimicrobial resistance in bacteria. Methicillin-resistant *S. aureus* has been known for decades, but its incidence is growing, even among nonhospitalized patients. Multidrug-resistant gram-negative bacteria are increasingly becoming a problem, limiting treatment options. Vancomycin-resistant *Enterococcus faecium* has become a major problem in nosocomial infections in the United States, but thus far has been rarely seen in osteomyelitis. The greatest concern is the development of vancomycin-resistant *S. aureus*, which has now been identified in patients in Japan, the United States, and Europe. Although this has not yet been reported as a cause of osteomyelitis, bone infections with this organism could be catastrophic, as no effective antibiotics for this infection are yet available.

### SYSTEMIC ANTIBIOTIC THERAPY

Antibiotic therapy is an adjunct to good surgical management, which includes adequate debridement and wound management. There has been a recent surge in the number of antibiotics available for the treatment of osteomyelitis. The beta-lactam antibiotics, such as penicillin and cephalosporin, are effective and relatively safe antimicrobials that can cover a wide range of gram-positive and gram-negative infections. The quinolones, however, have changed the treatment of osteomyelitis by providing oral drugs that achieve excellent serum levels and have good bone penetration.

The questions most often asked about the use of antimicrobials concern the choice of agent, the optimal route (intravenous, oral, or local), and the length of administration. The Gram stain, culture, and antimicrobial sensitivity tests are important guides in determining the specific antimicrobials to be used. Sensitivity testing not only helps to identify resistant organisms but also to guide the selection of the most active antimicrobial for the specific infection.

*Staphylococcus aureus* remains the most common cause of osteomyelitis. A semisynthetic penicillin (such as nafcillin) is the drug of choice for most staphylococcal infections. Alternative choices could include a first-generation cephalosporin (such as cefazolin (Ancef)), clindamycin, or a quinolone. Vancomycin is less active against *S. aureus* than the penicillins and should not be used except in the case of patient allergy to the beta-lactams or for the treatment of methicillin-resistant *S. aureus*.
Rifampin may be used in combination with one of the other agents for synergy.

Infections with the gram-negative bacilli can be treated with a penicillin plus beta-lactamase inhibitor combination [such as piperacillin-tazobactam (Zosyn)], a cephalosporin [such as ceftolozane (Cliformin) or ceftazidime (Rocephin)], an aminoglycoside, or a quinolone. For infections with P. aeruginosa, treatment with an antipseudomonal beta-lactam (such as piperacillin, ceftazidime, or ceftazidime) together with an aminoglycoside (such as tobramycin, which is the most effective against Pseudomonas) still represents the gold standard of therapy. Although successful treatment with a single agent, such as ceftazidime, has been reported (1, 16), treatment failures with single-agent therapy have been noted, including some cases associated with the emergence of resistance.

The quinolones are a major addition to the antimicrobials available for the treatment of osteomyelitis. Currently available quinolones may be useful in the treatment of osteomyelitis include ciprofloxacin, ofloxacin, and levofloxacin. They have a broad spectrum of activity including S. aureus and streptococci (with the newer quinolones such as levofloxacin having much better activity against the gram-positive organisms than ciprofloxacin), the aerobic gram-negative enteric bacilli, and P. aeruginosa.

One of the most important advantages of the quinolones is the fact that oral administration results in levels similar to those obtained with intravenous administration, suggesting that oral therapy can replace intravenous therapy, at least in some instances (17, 58). Since the incidence of adverse reactions to these drugs is low, they may be used in place of more toxic antimicrobials such as the aminoglycosides.

The treatment of osteomyelitis caused by Mycobacterium tuberculosis has been influenced by the rise in drug-resistant organisms. The current treatment recommendations are starting with three or four drugs (isoniazide, rifampin, pyrazinamide, and ethambutol), depending on the level of isoniazide resistance in the community. If cultures show that the organism is sensitive to isoniazide and rifampin, therapy can continue with isoniazide and rifampin for a minimum of 6 months, although longer regimens (9–12 months) are probably required (55).

Fungal infections have traditionally been treated with amphotericin B, which was the only agent effective against deep fungal infections. Although it is often effective, there are significant adverse effects associated with the administration of amphotericin B, including fever, chills, and nausea during administration, and renal insufficiency or failure with potassium and magnesium wasting. Newer agents such as fluconazole and itraconazole have excellent activity against many of the fungal organisms and far fewer side effects.

Because of the large number of new antimicrobials available, the problem of increasing resistance among organisms, and the potential for significant adverse reactions with many of the drugs, it is imperative that an infectious disease consultant help with the selection of specific antibiotic therapy and the monitoring of the patient for adverse reactions. Table 133.1 lists commonly used antimicrobials (also see Chapter 132).

Table 133.1. Commonly Administered Antimicrobials

### TOPICAL ANTIBIOTIC THERAPY

Topical antibiotic therapy is an old concept. Hippocrates and later Galen used medicinal ointments that included honey, a bactericidal agent, in the treatment of open fractures. In the early 1900s, Lord Lister, with good success, used phenol-soaked compresses to combat the microorganisms believed to be responsible for infection (35). He later introduced the use of carbolic acid as an antiseptic. Following the discovery of the sulfonamides, sulfa powder in wounds was popular among war surgeons. The major changes of today are the choice of the agent used and the development of new vehicles for delivery.

Most orthopaedic surgeons use a topical antibiotic solution for irrigation of infected wounds at the time of surgery. Although any antimicrobial could be used, the most commonly used agents are polymyxin (1 million units/L of saline) and bacitracin (50,000 units/L of saline).

Closed-suction antibiotic, high-volume irrigation systems have been used for ingress and egress, usually administered for a period of 3 to 21 days. The main deterrent to this mode of administration has been the emergence of new organisms, usually hydrophobic gram-negative organisms (10, 29, 47). The overall success for antibiotic irrigation has been shown to be the same as for antibiotic-impregnated polymethylmethacrylate (PMMA) beads (62). Therefore, tube-suction irrigation has been abandoned by many surgeons. If this system is used, adhere to every means possible to prevent contamination. The risk of secondary contamination increases with the length of usage of the irrigation system. It is advisable to use Silastic drains and to place the tubes on suction or egress for 24 hours before removing the system. This procedure will remove all of the fluid and hematoma present and will collapse the dead space, thereby precluding the possibility of abscess formation. I do not recommend the use of suction-irrigation systems.

Antibiotic-impregnated PMMA can be used to achieve local delivery of high concentrations of antibiotics. Among the advantages of antibiotic beads are low systemic levels of antibiotics, resulting in a lower potential of systemic toxicity, decreased need for systemic intravenous therapy, and decreased length of hospital stay. The disadvantages are that it requires a closed wound for the development of high local levels of antibiotics. Moreover, it may act as a foreign body, especially in the presence of resistance to the antibiotic in the vehicle, such as gentamicin or tobramycin.

The use of antibiotic-impregnated PMMA in total hip implants has been advocated (4, 5, 41). Klemm and other investigators have reported good results with the use of gentamicin-impregnated polymethylmethacrylate beads (Septopal) for the treatment of chronic osteomyelitis (30, 31). Unfortunately, the United States Food and Drug Administration (FDA) approval of factory-made gentamicin beads (Septopal) has been indefinitely delayed, leading many surgeons to make their own beads using bead molds (13).

Numerous studies have evaluated the in vitro elution characteristics of PMMA combined with antibiotics. The majority of studies have evaluated gentamicin, but as it is no longer commercially available in powder form for injection in the United States, physicians now use tobramycin and vancomycin since they are active against the most common organisms leading to prosthetic joint infections and osteomyelitis. Antibiotic elution from antibiotic-impregnated PMMA is proportional to the surface area of the cement (65, 69) and affected by the type and concentration of the antibiotic used, the brand of PMMA cement, and the amount and turnover of the surrounding fluid (69). Studies have shown that antibiotics elute better from beads than from spacers, and better from palacos cement than from simplex cement, and tobramycin achieves better levels than vancomycin (20, 33, 36).

Overall, the results of treatment with antibiotic-impregnated PMMA beads are encouraging, so the use of these in selected cases seems appropriate (Fig. 133.1). A different vehicle for the delivery of local antibiotic therapy may improve results and lessen the disadvantages associated with this therapy. Various biodegradable antibiotic delivery systems are now being evaluated but are still in the investigational stage.
abscess with sequestra. Within the distal third of the tibia and a serpiginous area of low intensity consistent with osteonecrosis. A biopsy had been performed previously. At surgery, she had an

CLASSIFICATION OF OSTEOMYELITIS

Cierney et al. proposed a staging system for adult osteomyelitis based on anatomic type and physiologic class (7,8). The four anatomic types are type I, medullary osteomyelitis; type II, superficial osteomyelitis; type III, localized osteomyelitis; and type IV, diffuse osteomyelitis.

The three physiologic classes deal with the condition of the host. An "A" host has good systemic defenses with good local vascularity and a normal physiologic response to infection and surgery. A "B" host is a compromised host with either local, systemic, or combined deficiency in wound healing and infection response. A "C" host is a patient who is not a surgical candidate, requires suppressive or no treatment, who has minimal disability, or for whom the treatment or results of treatment are more compromising than the disability caused by the disease itself.

DIAGNOSIS

A diagnosis of acute osteomyelitis should be considered an emergency. The presenting signs and symptoms may vary with the severity of the infection. Symptoms include fever and chills, general malaise, irritability, pain, and swelling. With lower extremity involvement, there is either a limp or an inability to bear weight. An infant with upper extremity involvement may exhibit pseudoparalysis; older children and adults with upper extremity involvement complain of pain on movement or use of the extremity.

It is important to localize the point of maximum tenderness, which is usually warm and swollen. In children it is generally in the metaphyseal region. It is also important to evaluate the adjoining joint for evidence of septic arthritis, which can occur as an extension of the adjoining osteomyelitis. Osteomyelitis involving the neck of the femur, talus, and humeral head often leads to sepsis of the joint because these foci are located within the joint capsule.

Once the point of maximum tenderness is localized, aspirate the area, and send the pus or fluid obtained for Gram stain, culture, and sensitivity studies. If tuberculosis or a fungal infection is suspected, obtain an acid-fast stain and tuberculosis and fungal cultures. When a joint effusion is present or joint involvement is suspected, aspirate the joint and confirm with an arthrogram. The arthrogram helps document the location of the aspiration and is useful for positive as well as for negative aspirations, since it may also identify joint capsule rupture. Aspiration of the hip joint under ultrasound guidance is very helpful in children and adults.

The white blood cell count is generally elevated, depending on the severity of the infection, with an increase in immature or band cells. The erythrocyte sedimentation rate and the C-reactive protein are usually elevated. Obtain blood cultures in all cases of acute hematogenous osteomyelitis and in chronic osteomyelitis exacerbated by fever and bacteremia.

Roentgenograms taken early in the disease process generally show soft-tissue swelling. Bony changes are not present until 7–10 days after the onset of infection. Radionuclide bone scanning using radioactive-labeled isotopes, such as technetium-99m and, more specifically, gallium citrate-67 and indium-111-labeled white blood cells, is helpful in localizing the area of involvement and in helping diagnose the condition.

Plain technetium, sequential technetium-gallium imaging, and indium-labeled leukocyte scintigraphy are the studies most commonly used. Indium 111-labeled leukocytes have been reported by a number of investigators as being more useful than other imaging in osteomyelitis complicated by fractures and nonunions (11,38,40,63) (see Chapter 132). Aspiration is used for the diagnosis, especially when there is no drainage or sinuses, and in some cases bone biopsy may be necessary.

Magnetic resonance imaging (MRI) has added a new dimension to the diagnosis, localization, and characterization of the extent of infection. MRI has been reported by Modic et al. to have a 94% accuracy in diagnosing spine infections (40). T1- and T2-weighted images are the initial screening techniques for diagnosing osteomyelitis. The MR finding in osteomyelitis on T1-weighted image sequences is a low signal intensity due to a dark marrow signal and an increased signal intensity due to a bright marrow signal on the T2-weighted image sequences (Fig. 133.3). MRI has decreased the need for bone scanning and provides more useful information. Do sinograms whenever there is a sinus tract or open draining area from which the depth and extent of the infection can be determ

Figure 133.1. Anteroposterior roentgenograms of a 46-year-old man with chronic osteomyelitis. The patient was treated with debridement followed by insertion of aminoglycoside-impregnated methylmethacrylate beads and a local muscle flap.

Figure 133.3. T1-weighted images of a 44-year-old woman with systemic lupus erythematosus and hematogenous osteomyelitis. There is decreased signal within the distal third of the tibia and a serpiginous area of low intensity consistent with osteonecrosis. A biopsy had been performed previously. At surgery, she had an abscess with sequestra.
**Figure 133.3.** These T2-weighted images of a 15-year-old boy show increased signal from the ankle to the mid tibia. There is increased signal in the adjacent soft tissues about the ankle and tibia. There is a minimal ankle effusion present. At surgery, the patient had an intramedullary abscess of the metaphysis and distal tibia.

**Figure 133.4.** Anterior (A) and posterior (B) roentgenograms of a sinogram in a 21-year-old man with chronic osteomyelitis that tracks into the intramedullary cavity.

**Figure 133.5.** Lateral radiograph (A) of a 15-year-old boy shows a subperiosteal abscess that was aspirated and injected with contrast material. Anteroposterior (B) and lateral (C) radiographs of a 9-year-old child show contrast material in the subperiosteal area and within the medullary cavity after pus had been aspirated. The contrast material demonstrates the extent of the abscess.

**PRINCIPLES OF TREATMENT OF INFECTED UNUNITED FRACTURES AND NONUNIONS**

The principles of treatment are infection control, stabilization of the fracture, soft-tissue coverage, and bone graft of ununited fractures and large bone defects.

Infection control includes irrigation and debridement, culture and sensitivities, and antibiotic therapy. In chronic osteomyelitis, obtain aerobic, anaerobic, and fungal cultures. Recent studies have advocated taking of multiple deep cultures from purulent material, soft tissue, and bone (51,56). Marrie and Costerton postulated that different organisms may be growing in isolated microenvironments. Sampling differences and bacterial viability may influence the culture results (37).

Stabilization of the ununited fracture or nonunion is essential. Soft-tissue coverage may require the use of local muscle flaps and free vascularized muscle flaps for soft-tissue defects or an inadequate soft-tissue envelope after control of the osteomyelitis. Local muscle flaps and free vascularized muscle transfers also help by bringing in a new blood supply, which is important in host defense mechanisms, antibiotic delivery, and osseous and soft-tissue healing (46). For the tibia, use the gastrocnemius muscle for proximal-third defects, the soleus for middle-third, and for the distal-third, free vascularized muscle transfers.

For local muscle transfers, it is important to assess the muscle preoperatively and not to transfer damaged muscle. Also avoid using crushed or badly damaged muscle, as flap necrosis or flap complications may result. In these cases, use free vascularized tissue transfer. Do preoperative angiograms on patients whose vascular status has been altered from any cause.

**SURGICAL CONSIDERATIONS**

**TOURNIQUETS**

Apply a tourniquet whenever possible except in patients with sickle cell disease or significant peripheral vascular disease. The tourniquet improves hemostasis and thus facilitates identification of the infection process. In acute cases with swelling, cellulitis, or abscess formation, elevate the extremity for several minutes before inflating the tourniquet. In chronic osteomyelitis without significant cellulitis or abscess formation, use an elastic bandage to extravasate the extremity before inflating the tourniquet.

**DEBRIDEMENT**

Thorough debridement of all sequestra and necrotic and desiccated bone is essential. Do not remove viable infected bone, so as not to create large bony defects. It is not necessary to debride viable infected bone. Dyes and tetracycline labeling have been used as a means of identifying necrotic bone, but I have not found these techniques to be useful.

Clinically dried out, exposed, desiccated bone is darker than normal and should be debrided. Necrotic bone that has not been exposed may appear at surgery more yellowish than viable bone, which is whitish. The main finding is that viable bone bleeds, whereas necrotic bone does not.

Use of an osteotome to superficially shave the outer cortex of the questionable bone results in small areas of punctate bleeding. Some bone that may have been exposed to air may be viable; in these cases, the exposed outer cortex should be debrided with an osteotome down to good bleeding bone. Evacuate all pus and abscess, and remove all necrotic and infected soft tissue.

**IRRIGATION**

Use copious amounts of irrigating fluid, which cleanses the area of purulent exudate, loose soft tissue, and bony fragments, and decreases the bacterial count. I use 10 L of irrigating fluid for most infected wounds. I use 2 L of antibiotic solution containing 50,000 units of bacitracin and 1 million units of polymyxin per liter as the final irrigating solution. Other antibiotics can be used for topical irrigation as well.

**WOUND MANAGEMENT**

The decision to leave a wound open or to close it requires careful judgment. In the majority of acute infections, and in all cases in which there is associated abscess formation with cellullitis and swelling, the wound should be left open. In some cases of early postoperative infection, the wound may be closed over drainage tubes, as long as the wound is thoroughly clean and the infection is not anaerobic.

In cases of chronic osteomyelitis in which there is no significant cellulitis or abscess formation and in which the wound has been adequately debrided and converted to
a clean wound, the wound may be closed over drainage tubes. In some cases in which bone or metal will be exposed if the wound is left open, a partial closure over the bone or metal may be desirable, as long as an adequate pathway has been provided for drainage. When there is any doubt, it is safest to leave the wound open. If the wound is closed, the wound site must be examined daily for any signs of infection; if such signs appear, the wound must be opened.

Many wounds heal nicely by secondary intention. In the case of large wounds or when delayed closure is preferable, do not attempt closure until two criteria are met. First, the wound should appear clinically healthy, with clean granulating tissue and without any purulent exudate or necrotic tissue. If infected necrotic tissues are present, redebride the wound until it appears healthy. Second, once the clinical appearance of the wound is clean, take quantitative tissue cultures and do Gram stains. Wounds with either a positive Gram stain or quantitative tissue cultures with a bacterial count greater than 10^5 organisms should never be closed. (A positive Gram stain implies a bacterial count of greater than 10^5 organisms.)

These wounds should be considered infected and reassessed for further surgical debridement and the appropriateness of the systemic antibiotic therapy. With experienced surgical teams, tissue cultures are not routinely performed. It has been our practice to do a thorough initial debridement followed by an en bloc excision of the wound at closure or muscle transfer.

In secondary closure of wounds, it is important to redebride the wound at the time of closure and to do en bloc resection of the granulating tissue for several reasons. First, although the bacterial count is low, these tissues should still be considered contaminated; debridement will further reduce the bacterial count and thereby diminish the chance of infection. Second, debridement allows for cleaner, healthier tissue to be approximated by wound closure or covered by muscle transfer.

**DRAINS**

When the wounds are closed, Silastic (Jackson-Pratt) or polyethylene (Hemovac) drains may be used. I prefer the Jackson-Pratt drains. Penrose drains, made of rubber, are the most reactive, and if left in for long periods can cause foreign-body granulomas. Do not use Penrose drains in orthopaedic infection management.

Remove the suction drain in 48–72 hours. The drain allows the removal of all hematoma and tissue fluid, and the collapse of the potential dead space. The drains should be removed under sterile conditions and the tip cut off and sent for culture and sensitivity tests.

The drain tends to attract whatever bacteria are present because it is a foreign body and because tissue fluids are removed through it. In general, a positive culture of the drain tip is a bad prognostic sign: It means that bacteria remain behind. Monitor the clinical course and wound site closely; if any clinical signs of wound infection reappear, it may be necessary to consider redebridement and reassessment of antibiotic therapy.

**WOUND PACKING**

The purpose of leaving a wound open is to allow drainage. Make certain, therefore, when packing wounds with gauze or other materials, that packing does not obstruct drainage. If it does, the purulent exudate will be retained in the wound, possibly causing tissue breakdown and necrosis with secondary cellulitis or even abscess formation. It is best to put wicks perpendicular to the open wound to allow free drainage. Wicks can be either povidone-iodine (Betadine)-soaked gauze, plain gauze, or fine-mesh gauze. The size varies with the size of the wound. The ends of the wicks should always protrude through the skin edges to allow easy access and removal and to prevent retention.

**ANTIBIOTIC BEAD POUCH**

Antibiotic-loaded beads were first introduced by Klaus Klemm for use in osteomyelitis (30,31). Henry, Seligson, and Ostermann introduced a physician-made antibiotic bead pouch for use in open fractures (25,43). This concept has been expanded, and I now use a physician-made antibiotic bead pouch during the interval between the initial debridement and the time of muscle transfer, a median of 4 days. Microbe-specific antibiotic(s) can be added to either Palacos or Simplex PMMA. I prefer Palacos: The antibiotic elution has been reported by some investigators to be better than Simplex. Although most antibiotics may be added to PMMA depending on the microbial sensitivity results, tobramycin and other aminoglycosides are the most commonly used antibiotics.

I use 2.4 g tobramycin to 40 g Palacos PMMA, an amount sufficient to make enough bead chains to fill large defects. I use a mold to make 6- or 7-mm beads strung on 24- or 26-mm wire. For those surgeons who make beads without a mold, the bead size should be small because increased surface area allows for better antibiotic elution. The beads are then covered by Tegaderm, Opsite, or an equivalent material. The advantages of the antibiotic bead pouch used in this fashion are high local antibiotic levels with low systemic toxicity and less chance for secondary contamination because the wound is covered. Also important is patient comfort, as dressing changes are not required, and there are decreased requirements for wound care.

**SURGICAL TECHNIQUES**

**HEMATOGENOUS OSTEOMYELITIS**

Hematogenous osteomyelitis is most often seen in infants, children, drug abusers, and immunosuppressed hosts. In 1894, Lexer injected laboratory animals with S. aureus organisms and then traumatized a bony area, causing infection to appear at that site (33). Hobo explained that the predilection for the metaphysis in acute osteomyelitis was due to the fact that the arteries in this location are end arteries, that there is slowing of the venous flow in the sinuses, and that phagocytosis is defective in this area (27).

Trueta later expanded on Hobo’s work (65). Once the metaphyseal region is seeded and exudate or pus forms, the suppurative process may then travel under pressure through the Volkmann canals into the subperiosteal region, extend itself within the medullary cavity, or spread into the epiphysis (Figs. 133.6, 133.7). It is not uncommon for the joint to be involved secondarily, especially a joint in which the metaphysis is intra-articular, such as the hip or shoulder. Often the abscess extends into the soft tissues as well (42,67).

Figure 133.6. Outline of the pathophysiology of hematogenous seeding. When under pressure, the exudate or abscess can extend through the Volkmann canals into the subperiosteal region, and from there into the intramedullary cavity or the epiphysis. (Modified from Hobo T. Zur Pathogenese der Akuten Haematogene Osteomyelitis, mit Berucksichtigung der Vitalfarbungslehre. Acta Sch Med Univ Imper Kioto 1921:4.1.)

In cases in which the disease is not diagnosed promptly or in which either inadequate or no treatment is given, the disease enters the subacute stage (Fig. 133.7). Because of the introduction of antibiotics and improved diagnostic and surgical techniques, the chronic stage and its sequelae are no longer seen as frequently as they used to be.
One question that arises in the treatment of acute hematogenous osteomyelitis is whether to treat all patients surgically. Unless clinical evidence of an abscess is present, I treat patients with systemic antibiotics and without surgery. However, the clinical situation must be repeatedly assessed during treatment. Many osteomyelitic processes are seen early in the disease process or represent a cellulitic process of the bone, and pus or the abscess phase may not occur.

Although some authors have not found it necessary to drill a window in cases of subperiosteal or soft-tissue-extended osteomyelitis, I routinely window the cortical bone for better debridement of the residual intramedullary abscess and necrotic bone and tissue (Fig. 133.8) (see Chapter 176).

**Cortical Windowing for an Acute Intramedullary Abscess of the Tibia**

- Using tourniquet control, make a longitudinal incision along the posterior border of the medial tibia and over the affected part of the tibia. If a subperiosteal abscess is present (more likely in a child than in an adult), incise the periosteum longitudinally over the abscess.
- If no subperiosteal abscess is found, observe the status of the cortex. The infected area is often soft and may be pitted, with or without obvious cortical destruction.
- Drill several holes through the cortex into the medullary canal. Unless the intramedullary abscess has already decompressed itself into the subperiosteum or soft tissues, pus will exude through these holes.
- Outline with a drill an elongated cortical window extending along the extent of the intramedullary abscess. The outlined elongated window should be centered in the posterior half of the anteroposterior diameter of the bone to allow for dependent drainage. The length of the window depends on the extent of the intramedullary abscess, and the width depends on the diameter of the bone. For children, use a 1- to 2-cm-wide window. After debridement of any obvious sequestrum and copious irrigation, insert a Betadine gauze into the wound and leave it open. A similar type of window of the femur is made for osteomyelitis of the femur.

**OSTEOMYELITIS FOLLOWING OPEN FRACTURES**

For acute osteomyelitis following an open fracture, it is important to assess the extent of the infection and to obtain a Gram stain, culture, and sensitivity test. Start appropriate systemic antibiotics, and take the patient to surgery for irrigation, debridement, and stabilization of the fracture if it is not already adequately stabilized (Fig. 133.9). The majority of fractures in the tibia can be stabilized with half-pin external fixation devices. Use a biplanar or delta frame for more stability if required.

**HINTS AND TRICKS**

Once the open fracture infection has been controlled and the fracture stabilized, perform cancellous autogenous bone grafting, particularly for fractures with bone deficiency and type III open fractures. Fracture healing, which facilitates infection control, is an important principle in the management of infected nonunited fractures and nonunions. Although many fractures heal in the presence of infection, infection interferes with the osteogenic process and may lead to nonunion by a number of mechanisms. The bacteria compete with osteogenic cells for oxygen and nutrients, activate enzymes deleterious to the osteogenic process, lower the pH, affect oxygen potential, interfere with the differentiation of osteogenic cells, and retard tissue maturation.

For both unstable infected open tibial fractures and type III infected open tibial fractures, I recommend early autogenous cancellous bone grafting through a posterolateral approach. Alternatively, if a muscle flap has been made anteriorly for soft-tissue coverage, an autogenous cancellous bone graft can be done anteriorly 6 weeks later, provided there is no evidence of recurrent infection.
Avoid making a cortical window directly under the skin incision; the soft tissues will not granulate over a cortical defect, and skin coverage therefore will not occur. A muscle transfer may then be necessary.

- Make the cortical window in the dependent one half of the anteroposterior diameter of the bone to allow for adequate drainage.
- Avoid making too large a cortical window, which can lead to pathologic fractures, especially if the width is excessive.
- In children, in whom the usual location for hematogenous osteomyelitis is the metaphysis, be careful not to damage the epiphyseal plate. Use roentgenograms intraoperatively to help locate the physis.
- If follow-up cultures are positive or if pus continues to drain, consider performing a second irrigation and debridement.
- Postoperatively, apply a posterior splint. A wound left open generally closes by secondary intention within 3 weeks.
- Recommend protected weight bearing in a cast or orthosis for 6–12 weeks whenever a cortical window is used.

Posterolateral Bone Grafting of the Tibia

Posterolateral bone grafting is particularly useful in achieving union of an infected nonunion or an infected fracture of the tibia. Freeland and Mutz have reported a 100% union rate in 26 patients with infected nonunions treated in this manner (44). I have achieved a union rate of approximately 91% in the treatment of 61 infected tibial nonunions (45).

The approach is used for the distal two thirds of the tibia. It was described by Harmon and is also used for tibia-pro-fibula grafting (43) (Also, see Chapter 3).

- Place the patient in either a prone or a lateral decubitus position. Identify the posterior border of the fibula and the lateral border of the gastrocnemius muscle.
- Using tourniquet control, begin an incision of appropriate length along the lateral border of the gastrocnemius and posterior to the fibula.
- Once you have cut through the subcutaneous structure, identify the peroneal muscles anteriorly and develop a plane between the peroneals and the posterior muscles consisting of the gastrocnemius, the soleus, and the flexor hallucis longus muscles.
- Now reflect the soleus and flexor hallucis longus posteriorly and medially to expose the posterior aspect of the fibula.
- Elevate the origin of the tibialis posterior muscle from the posterior aspect of the interosseous membrane. Locate the posterolateral border of the tibia and, using sharp dissection, expose the posterior surface of the tibia by stripping the muscles subperiosteally off the tibia. In the distal one third of the tibia, approximately four to five fingerbreadths above the tip of the lateral malleolus, an interosseous arteriole branch from the peroneal artery perforates the interosseous membrane and travels anteriorly to anastomose with the anterior tibial artery. Take care to protect this vessel. The posterior tibial neurovascular bundles lie between the tibialis posterior and flexor hallucis longus muscles and are not visible. The muscular branches of the peroneal artery lie within the peroneal muscles.
- Once the posterior aspect of the tibia is exposed (Figs. 133.10), prepare the tibia and the posterior aspect of the fibula for bone grafting by roughening up the cortex with either a burr or an osteotome. Be extremely careful not to disturb the fracture site so as to avoid contamination posteriorly.

Lay cancellous bone grafts posteriorly several inches above and below the fracture site and between the tibia and fibula across the interosseous membrane. The objective is to achieve not only union of the fracture site, but also a tibial–fibular synostosis (Fig. 133.11). A 1.5–2 oz medicine glass filled with cancellous bone is generally sufficient to repair a nonunion without bone loss.

- At this point, release the tourniquet and achieve hemostasis. Insert a Silastic drain. Allow the peroneal muscles and posterior muscle mass to return to their anatomic positions. Do not close the deep fascia.
- Close the subcutaneous tissues and skin with interrupted sutures.
- Remove the Silastic drains in approximately 48 hours and elevate the leg for 72 hours.
- Start full weight bearing to tolerance 7 days postoperatively if the patient is immobilized in a cast.
- If an external fixator is used for an unstable fracture, it can generally be removed at 6–8 weeks and a walking cast applied.
- Union generally occurs in 4–7 months, median time being 6 months.

**HINTS AND TRICKS**

- An arteriogram obtained before this procedure is performed can help determine what vessels are patent and where they are.
- Be aware of the location of the neurovascular structure.

**DEAD-SPACE MANAGEMENT**

It is important that soft-tissue and bony defects be filled to reduce the chance of continued infection and loss of function. Advances in microvascular techniques have made possible the transfer of muscle, myocutaneous, osseous, and osteocutaneous flaps to the soft-tissue and bony defects. Fitzgerald et al. reported a 93% success rate in the treatment of chronic osteomyelitis with local muscle flaps combined with thorough debridement and specific antimicrobial therapy (12). Our results using this technique have also been encouraging (46).

In general, for soft-tissue defects involving the proximal third of the tibia, use the gastrocnemius muscle; for those involving the middle third, use the soleus muscle; and for those involving the distal third, use a free-tissue transfer.

In cases of bony defects, perform autogenous cancellous bone grafting six or more weeks later. The muscle flap can be elevated and cancellous bone grafting performed underneath, provided there are no signs of infection (Fig. 133.12).
According to Weiland et al., the highest rate of recurrence of infection in free-tissue transfer in osteomyelitis is found in cases associated with a segmental bone defect \((70)\). It has been our experience that the fibula is the key factor in treating osteomyelitis with segmental bone loss of the tibia. If there is a bony defect or segmental loss of both the fibula and tibia with chronic osteomyelitis, an amputation is advisable. If the fibula is intact or without a bony defect, reconstruction of the bony defect is more likely to be successful. For defects up to 6 cm, autogenous cancellous bone grafting can be done (Fig. 133.13).

In larger defects, use a free vascularized osseous graft. A tibia-pro-fibula synostosis using the previously described posterolateral approach can be done when a free vascularized osseous graft or autogenous cancellous bone grafting of the defect is not possible (Fig. 133.14). The fibula hypertrophies with time, allowing for functional weight bearing.

Another procedure for dead-space management is the open cancellous bone grafting procedure described by Rhinelander (57) and by Papineau et al. (45). This procedure is useful when tissue transfer is not possible. **Open Cancellous Bone Grafting**

Open cancellous bone grafting has been effective in the treatment of infected bone defects. Papineau et al. (45), Roy-Camille et al. (59,60), Rhinelander (57), Higgs (26), Knight and Wood (32), Coleman et al. (9), Bickel et al. (2), and Green and Dlabal (19) have all reported favorable results. However, because of the associated long hospitalization time, long healing time, high complication rate, meticulous care required, and resulting unstable scar skin, I use it only if local muscle transfers or free-vascular tissue transfers with secondary cancellous bone grafting cannot be done.

There are three stages to this technique:

- Thorough debridement of all infected tissues, repeated as necessary; stabilization of the fracture with an external skeletal fixator
- Cancellous autogenous bone grafting into a defect lined with clean uninfected granulation tissue
- Skin coverage either by secondary epithelialization or, in larger defects, by split-thickness skin grafting

- Debride all infected soft tissue and sequestra, and debride all necrotic bone to bleeding osseous tissue. Perform stabilization using an external skeletal fixator.
- When exposed surfaces are covered with clean granulation tissue, pack finely morcelized autogenous cancellous bone into the defect created by the bone debridement or previous bone loss. The diameter of the graft should be slightly larger than the diameter of the bone being replaced, since the graft will tend to contract. Rhinelander recommends that the maximum graft thickness be 1.5 cm from the nearest granulation surface (57).
- Dress the wound with gauze and keep it moist with a physiologic irrigating solution such as Ringer’s lactate, either by intermittent soaking of the dressings or by a slow intravenous drip. The dressing, which should be changed daily, is to be soaked with physiologic solution until the wound is covered by epithelialization or, in some cases, by secondary split-thickness skin grafting (Fig. 133.15).
HINTS AND TRICKS

- Make sure all necrotic soft tissue and bone are debrided.
- Stabilize the fracture.
- There must be a clean granulating base before autogenous cancellous bone grafting is performed. Do a quantitative tissue culture and Gram stain. If the quantitative tissue culture yield is greater than $10^{-5}$ organisms, or if the Gram stain is positive (implying the presence of more than $10^{-5}$ organisms), do not perform the cancellous bone grafting. A count greater than $10^{-5}$ organisms is consistent with infection, in which case redebridement is necessary.

OSTEOMYELITIS IN THE PRESENCE OF INTERNAL FIXATION FOR FRACTURE STABILIZATION

Osteomyelitis in conjunction with internal fixation for fracture stabilization poses a special problem for the surgeon. Should the metal be removed or left in? The answer to this question is guided by such factors as the stage of fracture healing, the amount of stability provided, the amount of time since surgery, and the location of the fracture.

Gristina and Costerton reported that in 76% of prosthesis-related infections, microorganisms grew in a biofilm or glycocalyx that adhered to the surfaces of the biomaterials present (21). They suggested that infections in the presence of orthopaedic implants may be more resistant than normal to host defense mechanisms and to antimicrobial therapy.

If osteomyelitis develops in the presence of metal with a healed fracture, remove the metal. If the fracture is not united and the metal is not providing stability, remove the metal and restabilize the fracture. In the immediate postoperative period (within the first 1–6 weeks), retain the internal fixation device if it is stable and is required.

If the internal fixation device is stabilizing a nonunited articular fracture, retain it (Fig. 133.16). In general, for late infected nonunion of tibial shaft fractures with internal fixation, I recommend removal of the internal fixation device and stabilization with an external fixator. For late nonunion infections of the femur with plate fixation, I recommend removal of the plate and eventual stabilization with an intramedullary rod.

OSTEOMYELITIS OF THE METATARSAL HEADS AND PHALANGES FOLLOWING PUNCTURE WOUNDS OF THE FOOT

Pseudomonas has been reported to be the most common organism causing infection following nail puncture wounds of the foot. The treatment that produces the best results consists of surgical drainage, debridement, and curettage of the puncture wound in the bone, and debridement of all necrotic bone, along with specific antibiotic therapy. The antibiotic of choice for Pseudomonas infections is generally tobramycin, in combination with either piperacillin or a third-generation cephalosporin, depending on the sensitivity reports. Continue systemic antibiotics for approximately 3 weeks (Fig. 133.17, Fig. 133.18).
In most cases, use a plantar approach. A dorsal incision can be used when there is joint involvement, provided that debridement of the plantar surface of the metatarsal head or proximal phalanx is accomplished.

**Planter or Hoffman Approach**

- Make a plantar transverse incision distal to the weight-bearing area of the metatarsal heads but proximal to the web space of the toes. Carry the incision down through the subcutaneous tissues and identify the flexor tendons, which should be retracted to expose the involved metatarsal head.
- Incise the periosteum and elevate it to expose the proximal metatarsal; generally, the periosteum has been destroyed and this latter step is not necessary.
- Identify the area of osteomyelitis, and curet and debride the lytic infected bone. If there has been extensive destruction of the metatarsal head, the head can be excised through this approach.

**HINTS AND TRICKS**

- Be certain to debride all necrotic tissue.
- Always curet the bony puncture site when it is identifiable because this site could be a source of continued infection.

**Dorsal Incision**

- Make a longitudinal incision over the affected joint. Retract the extensor tendons. Identify the joint capsule and incise it longitudinally. Debride the joint of any necrotic tissue.
- Next, free the soft tissue from the plantar surface of the metatarsal; debride any necrotic bone and tissue, and curet the puncture site.
- Finally, irrigate the wound with copious amounts of irrigating fluid, and leave a small Betadine gauze or wick in the wound.

**OSTEOMYELITIS OF THE METATARSAL**

The metatarsals are most likely to be infected in diabetic patients or persons who have open fractures. Depending on the extent of the infection, local debridement of all soft tissue and bone may be satisfactory. In more extensive infections in which the entire metatarsal is necrotic, it may be necessary to remove it.

- Make a longitudinal incision over the involved bone extending from just distal to the distal row of tarsal bones to the middle of the proximal phalanx of the involved toe.
- Identify the extensor tendons and retract them.
- Identify the involved metatarsal, incise the periosteum longitudinally, and strip it and all soft tissues from the bone.
- Resect the entire shaft or part of the shaft as indicated. In children, avoid injury to the physis.

**HINTS AND TRICKS**

- Irrigate the wound with copious amounts of irrigating fluid. Pack the wound loosely with a Betadine gauge or a fine-mesh gauze and leave a wick protruding from the wound. When the infection is more localized, use a smaller longitudinal incision over the involved metatarsal.
- Apply a below-the-knee splint and dress the wound.

**OSTEOMYELITIS OF THE CALCANEUS**

Osteomyelitis of the calcaneus can be extremely difficult to eradicate and requires adequate, thorough debridement. In early involvement, extensive local debridement and curettage are usually sufficient. With extensive involvement of the calcaneus, resection of the diseased area is necessary to eradicate or control the infection. Osteomyelitis occurring either medially or laterally in the calcaneus usually follows pin-track infections, gunshot wounds, or open fractures.

Medial and lateral approaches to the calcaneus are useful in draining a localized abscess, curetting the infected bone tissue, doing a local resection, and windowing the bone cortex for an osteomyelitic abscess.

In osteomyelitis involving the plantar surface of the calcaneus, use the approach described by Gaenslen, with modifications. Gaenslen divided the calcaneus with an osteotome from posterior to anterior, thereby exposing the inside of the bone. He used this technique primarily to treat hematogenous osteomyelitis.

The technique has a very serious drawback, however, in that it creates a fracture, which could cause an infection to continue, leading to extensive bone loss. Therefore, avoid splitting the calcaneus when you plan to preserve it. Excision of the calcaneus through this approach, especially when there is a wound or fistula on the weight-bearing surface of the heel, works well.

- With the patient prone, make a longitudinal incision centered in the midline of the heel. Start the incision just inferior to the insertion of the Achilles tendon on the tuberosity, and extend it plantarward approximately to the level of the base of the fifth metatarsal.
- Incise the plantar aponeurosis in a plane between the abductor digiti quinti and flexor digitorum brevis muscles. Visualize the lateral plantar artery and nerve in the distal aspect of the wound and retract them medially.
- Expose the quadratus plantar muscle and split both it and the long plantar ligament longitudinally. The plantar surface of the calcaneus is now exposed. For localized infection use a curet to remove sequestra, infected tissue, and sinuses. For more extensive involvement use an osteotome to resect the involved bone parallel to the plantar surface of the foot. After debridement and copious irrigation, place a Betadine-soaked gauze dressing in the wound and leave the wound open.
sores.

Persons. In adults, osteomyelitis usually occurs following open fractures, bone-grafting procedures, or, in debilitated patients confined to bed, secondary to pressure

OSTEOMYELITIS OF THE ILIUM

Posterolateral Approach

The predisposing factors leading to osteomyelitis of the femur are very important in its management. For hematogenous osteomyelitis, windowing of the cortex as described in this chapter is the preferred method of treatment.

Postero lateral Approach

Use either a lateral decubitus position or turn the patient slightly to elevate the involved extremity. This approach provides access to the entire femoral shaft.

Make an incision from the base of the greater trochanter distally to the lateral femoral condyle, depending on the desired length of exposure. Incise the superficial fascia and the fascia lata along the anterior border of the iliotibial band.

Expose the vastus lateralis muscle and retract it anteriorly. Continue along the anterior surface of the lateral intermuscular septum, which attaches to the linea aspera.

Expose the periosseum and incise it longitudinally. Then use a periosteal elevator to expose the bone. Debride the area of infected necrotic tissue and bone.

In cases of nonunion in which a plate is present and the infection is seen late, remove the plate and apply an external fixation device. Follow with an autogenous cancellous bone-grafting procedure when the infection is controlled.

Identify the common peroneal nerve in the proximal part of the wound; it crosses under the peroneus longus just distal to its attachment to the lateral surface of the head of the fibula. Identify the fascial plane between the soleus muscle and the peroneal muscles anteriorly, and carry the dissection down to the fibula.

Retract the peroneal muscles anteriorly, and expose the fibula by incising the periosteum. Take care not to injure the branches of the deep peroneal nerve, which lie on the deep surfaces of the peroneal muscles at the neck of the fibula and proximal 5 cm of the fibula. Now expose the fibula, and debride or resect the infected area.

OSTEOMYELITIS OF THE FIBULA

Depending on the extent of the infection, it is safe to excise the proximal three fourths of the fibula, provided the fibular collateral ligament and the biceps femoris tendons are inserted into the tibia when this area of bone is sacrificed. The distal one fourth should not be excised, because excision would lead to impaired function of the ankle, and deformity. If it is necessary to remove this part, a tibial–talal fusion will be necessary later.

Make a longitudinal incision, starting on the posterior border of the fibula from the head of the fibula and extending distalward as needed. This incision can be carried down the entire length of the fibula.

Identify the common peroneal nerve in the proximal part of the wound; it crosses under the peroneus longus just distal to its attachment to the lateral surface of the head of the fibula. Identify the fascial plane between the soleus muscle and the peroneal muscles anteriorly, and carry the dissection down to the fibula.

Debride the area of infected necrotic tissue and bone. Don't be hesitant to resect all infected necrotic bone. Be careful of the lateral planatar neurovascular structures.

The distal one fourth of the fibula is subcutaneous and can be easily exposed by a longitudinal incision along the posterior border of the fibula.

A Betadine-soaked gauze strip can be loosely placed in the wound.

Apply a long posterior molded splint. Dress the wound daily.

OSTEOMYELITIS OF THE PATELLA

Expose the patella through a longitudinal skin incision that starts just proximal to the patella and extends distally to the inferior pole. Carry the incision down through the subcutaneous tissue and fascia to the periosteum.

Incise the periosseum and elevate it with a periosteal elevator. Curette and debride the involved area of bone.

In cases of extensive involvement of the patella, either part or all of the patella can be removed. In cases in which the knee joint is involved, irrigate the knee with 10 L of irrigating fluid. Close the joint capsule over Silastic drainage tubes, which are removed in 48–72 hours.

OSTEOMYELITIS OF THE FEMUR

The predisposing factors leading to osteomyelitis of the femur are very important in its management. For hematogenous osteomyelitis, windowing of the cortex as described in this chapter is the preferred method of treatment.

Posterolateral Approach

Use either a lateral decubitus position or turn the patient slightly to elevate the involved extremity. This approach provides access to the entire femoral shaft.

Make an incision from the base of the greater trochanter distally to the lateral femoral condyle, depending on the desired length of exposure. Incise the superficial fascia and the fascia lata along the anterior border of the iliotibial band.

Expose the vastus lateralis muscle and retract it anteriorly. Continue along the anterior surface of the lateral intermuscular septum, which attaches to the linea aspera.

Expose the periosseum and incise it longitudinally. Then use a periosteal elevator to expose the bone. Debride the area of infected necrotic tissue and bone.

In cases of nonunion in which a plate is present and the infection is seen late, remove the plate and apply an external fixation device. Follow with an autogenous cancellous bone-grafting procedure when the infection is controlled.

In the middle third of the thigh, take care to identify and ligate the second perforating branch of the profunda femoris artery and vein, which travel transversely from the biceps femoris to the vastus lateralis. Avoid damaging the sciatic nerve and profunda femoris artery and vein by not dividing the long and short heads of the biceps femoris muscle.

OSTEOMYELITIS OF THE ILIUM

Infection involving the ilium can occur on the medial, or inner, cortex and on the lateral, or outer, cortex, or on both. Hematogenous seeding is more common in young persons. In adults, osteomyelitis usually occurs following open fractures, bone-grafting procedures, or, in debilitated patients confined to bed, secondary to pressure sores.

Make an incision along the crest of the ilium extending the length of the infected area. Extend the dissection through the subcutaneous tissues to the crest.

Incise the periosseum over the top of the crest and subperiosseously strip the muscles from the lateral cortex of the iliac wing. Identify the abscesses, if one is present, and the extent of bone involvement. Drain the abscess and debride all necrotic bone. Window the cortex as necessary. Be careful of the lateral femoral cutaneous nerve, which normally lies just medial to the anterior superior iliac spine. Perform local resection of the ilium for extensive local involvement, especially in chronic osteomyelitis (Fig. 133.20).

Figure 133.19. Lateral radiograph of a 42-year-old man demonstrates extensive destruction of the calcaneus by osteomyelitis. A marking pen outlines the area of bones to be resected.

HINTS AND TRICKS

- Debridement is the key. Don't be hesitant to resect all infected necrotic bone.
- Be careful of the lateral planatar neurovascular structures.

Figure 133.20. A: Anteroposterior view of the ilium and hip showing a sinogram tract down to the ilium. This 44-year-old woman developed chronic osteomyelitis of the ilium following an open fracture. She had undergone multiple previous procedures. B: Radiograph after local resection of the ilium.
OSTEOMYELITIS OF THE ISCHIUM AND PUBIS

Osteomyelitis involving the ischial tuberosity is usually encountered in paraplegics or patients who are bedridden and develop pressure sores with secondary infection, necrosis, and osteomyelitis. In these infections, it is necessary to debride all necrotic tissue, after which the infected ischial tuberosity can be resected with an osteotome and mallet. Irrigate the wound copiously and leave it open, with Betadine-soaked gauze inserted into it to allow for drainage. In paraplegic patients, soft-tissue transfers are often necessary following infection control.

Abscesses in the ischiorectal fossa or beneath the obturator externus or internus often develop with osteomyelitis of the pubis and ischium.

OSTEOMYELITIS OF THE RADIUS AND ULNA

The ulna and the radius are most likely to become infected after open reduction and plating of fractures.

- Because the posterior surface of the ulna lies subcutaneously essentially throughout its length, expose the ulna by a skin incision carried down through the fascia and periosteum.
- Approach the radius in its distal third by the anterior approach, as described by Henry (24). Expose the proximal fourth of the radius with an anterior Henry incision or an extended Thompson approach.
- The middle two thirds of the radius can then be exposed by the Thompson approach (64) (see Chapter 1).

OSTEOMYELITIS OF THE HUMERUS

In adults, osteomyelitis of the humerus most commonly follows internal fixation of the humerus. Often, draining sinuses are present (Fig. 133.21).

![Figure 133.21. A sinogram tract down to metal and bone. The patient had persistent drainage for 7 months following open plating of the humerus. Notice that the fracture is healed.](image)

After assessing the extent of the infection, expose the humeral shaft through an anterolateral approach (see Chapter 1). Make a skin incision along the anterior border of the deltoid muscle, extending it distally along the lateral border of the biceps muscle to within several inches of the elbow joint. Identify the cephalic vein and ligate it.

- Retract the deltoid laterally and the biceps medially to expose the proximal shaft. Distal to the deltoid insertion, identify the brachialis and split it longitudinally to the bone, retracting the lateral half laterally and the medial half medially. The radial nerve is protected by the lateral half of the brachialis muscle. In the distal third of the exposure, identify the radial nerve, which lies between the brachioradialis and brachialis muscles, and protect it. Avoid injury to the musculocutaneous nerve.

Debride all infected and necrotic bone and soft tissue. If the humerus is unstable, remove the internal fixation and stabilize with external fixation. Leave the wound open.

ILIZAROV PROCEDURE

In osteomyelitis, the Ilizarov procedure has been found to be useful for the treatment of extensive bone loss problems or for angulatory nonunions (44) (Fig. 133.22). A more extensive discussion of the Ilizarov technique is presented in Chapter 32.

![Figure 133.22. Correction of deformity and subsequent healing process in a 29-year-old man with an infected nonunion of the tibia in marked varus, treated with the Ilizarov technique.](image)

ACKNOWLEDGMENT

I want to thank Dr. Paul Holtom, Associate Professor of Clinical Medicine and Orthopaedic Surgery, section of Infectious Disease, University of Southern California School of Medicine, for his technical assistance in the antibiotic section of this chapter.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical outcome study.

The term pyarthrosis is a fusion of two Greek words—pyon, meaning pus, and arthrosis, meaning joint (110). Therefore, pyarthrosis by definition denotes a suppurative arthritis. In common medical usage, the term refers to pyogenic infections involving the synovial joints. Septic arthritis accounts for 0.2% to 0.7% of hospital admissions and continues to be a cause of an orthopedic emergency that can lead to morbidity and mortality (83).

PATHOPHYSIOLOGY

Organisms may infect joints through several different mechanisms, including hematogenous spread from a distant source and spread from an adjacent focus of infection, for example contiguous osteomyelitis (6). Direct inoculation through a penetrating injury is another means, as is intra-articular injection and or a surgical procedure.

Infection of a synovial joint is an interaction between the host and the infecting organism. Factors important to this interaction include general host factors, local host factors, and the quantity and virulence of the infecting organism. General host factors that predispose individuals to septic arthritis include defects in the immune system (e.g., hypogammaglobulinemia), quantitative and qualitative white blood cell deficiencies, cancer, immunosuppression caused by chemotherapeutic agents, and severe chronic illness such as liver and kidney disease, rheumatoid arthritis, systemic lupus erythematosus, diabetes mellitus, sickle cell anemia, and alcoholism (5,20,71,78,86,87,117). Any distant focus of infection that induces recurrent bacteremia may predispose a patient to joint sepsis; sources include chronic sinusitis, bronchiectasis, and intravenous drug abuse (81).

Local joint factors are also important. Septic arthritis is more common after previous joint trauma, and a history of prior arthritis increases the risk of septic arthritis in the same joint (31,71,87,103). In rheumatoid arthritis, the increased risk of superimposed pyogenic arthritis is related to local factors (e.g., chronic hyperemia, a protein-rich inflammatory exudate within the joint, or local steroid injection), as well as generalized host factors (e.g., humoral and white blood cell deficiencies, the use of systemic immunosuppressive agents, and general debility) (6,36,66,69,71,85,114-117).

Other localized arthritides that have been associated with an increased incidence of septic arthritis include degenerative joint disease, Charcot arthropathy, and crystal-induced arthritis (gout and pseudogout) (22,61,64). The incidence of local infection is also increased after the implantation of various biomaterials commonly used in orthopaedic surgery (62). In particular, methylmethacrylate has been shown to have profound effects on local polymorphonuclear leucocyte chemotaxis and phagocytosis (61,62).

Synovial infection depends not only on host factors but also on the quantity and virulence of the infecting organism. Important factors in this respect include exotoxin, endotoxin, and enzyme production by the bacteria and the synovial membrane. These by-products, as well as bacterial debris, may also play a role by stimulating the host's immune system to produce the postinfectious arthritis syndrome (81-87).

Once the bacteria have reached the synovium, an acute inflammatory response ensues. Proteolytic enzymes are produced that degrade the proteoglycan matrix of the cartilage-ground substance and the collagen. These enzymes are released by the polymorphonuclear leucocytes and the lysosomes within the synovium (18,19,113,118). The bacteria themselves may also contribute to this depletion of cell matrix, even in the absence of inflammation (108).

If the septic process can be terminated before collagen loss has begun, the proteoglycan losses may be reversed. Enzymes released by the polymorphonuclear leucocytes and synovium, including collagenase, elastase, cathepsins, and other proteases, remove the proteoglycan matrix from the cartilage, destroy the collagen superstructure, and subject the chondrocytes to increased mechanical stress. As cartilage cells die, matrix formation is decreased, and a vicious circle ensues. The articular cartilage is eroded away, and the synovium becomes hyperplastic. A pannus of chronic granulation tissue may cover the joint surface. Fibrous or bony ankylosis may be the final result (49) (Fig. 134.1).

Figure 134.1. A: Photograph of the distal femoral articular surface in a normal rabbit. B: Photograph of distal femur of rabbit infected with Staphylococcus aureus and having antibiotic treatment started at 48 hours. Notice the irregularity and pitting in the weight-bearing portion of the articular cartilage. C: Distal femoral articular surface of a rabbit that was infected with S. aureus but did not receive antibiotics. Notice the severe degenerative arthritis that has developed.

CLINICAL PRESENTATION

Septic arthritis may affect any age group but has a propensity for neonates and infants, older adults, and patients who have a chronic, systemic disease, or a compromised immune system. Although virtually any joint may be involved, the large weight-bearing joints of the lower extremity are most at risk (5,6,20,31,46). The joints most commonly involved are the knee, hip, ankle, shoulder, wrist, and elbow (32). Usually, only a single joint is involved, but multiple joint involvement has been documented (5,31,52,74).

Patients with septic arthritis usually have a single joint that demonstrates the signs of acute inflammation: pain, swelling, heat, erythema, and loss of function. In
patients with chronic arthritis (e.g., rheumatoid arthritis), the diagnosis may be delayed because either the patient or the physician assumes that the clinical picture is a manifestation of an acute exacerbation of the chronic disease. Such was the case in 4 of 13 rheumatoid patients reported by Griswold et al. (36) In these instances, the physician must maintain a high index of suspicion of septic arthritis superimposed on a chronic illness.

Nongonococcal suppurative arthritis is most commonly secondary to hematogenous spread from a distant focus (5,70). Therefore, signs of septicemia, such as fever and tachycardia, may be present. In one study, during the first 24 hours of hospitalization, 78% of patients with septic arthritis were febrile. Chills and rigors are uncommon, and the temperature infrequently goes above 39°C (102.2°F) (31,70). The original focus of infection may be discovered after a careful history and physical examination. Special attention should be paid to the ears, nose, throat, and chest, as well as the inguinal, genitourinary, and gastrointestinal systems.

Gonococcal arthritis is probably the most common cause of bacterial septic arthritis (78). Whereas nongonococcal septic arthritis affects the very young, the elderly, or the immunocompromised, gonococcal arthritis affects healthy persons, usually younger than 40 years of age. The increasing female preponderance appears to be related to the asymptomatic carrier status. Women are often seen during pregnancy or just beginning the menstrual period, implicating local gynecologic and physiologic factors in the production of disseminated disease (70). Systemic signs and symptoms are variable (10,17,42,51,109).

The clinical picture is classically a migratory polyarthritis, which may eventually become monarticular. The knees, wrists, ankles, and hands are most often affected, and there may be an associated tenosynovitis. This classic clinical presentation of a migratory polyarthritis, tenosynovitis, and the characteristic vesicopapular skin lesions of gonorrhea is rarely seen in cases of nongonococcal septic arthritis. Look for other manifestations of gonorrhea, including signs of heart (endocarditis or myocarditis), central nervous system (meningitis), and liver involvement and conjunctivitis. Undertake an examination and cultures of the genitilia, rectum, oral pharynx, and other possible lesions (e.g., of the skin). Whereas joint aspiration and blood cultures are frequently positive in nongonococcal arthritis, this is not so in the case of gonorrhea.

The pediatric patient poses a special diagnostic problem. Whereas adults with septic arthritis can verbalize their pain, neonates and infants cannot. The child with a septic joint is generally systemically ill (34-35). Pseudoaparalysis of the limb and resistance to passive range of motion are frequently present and often suggest to the unwary that the child has a fracture. It is only after a more in-depth examination that the signs of inflammation are noted and focused to a single joint. The physician must always be suspicious of septic arthritis, especially in the immunocompromised child, the neonate who is small for gestational age, and at any age when invasive monitoring techniques are being used (34-36,68).

**DIAGNOSIS**

The history and physical examination pointing to a monoarticular inflammation should suggest septic arthritis. A white blood cell count from the peripheral blood is greater than 10,000 cells/mm³ in only 50% of patients and is occasionally helpful. The key diagnostic study is analysis and culture of the synovial fluid (51,66,70). Aspirate the fluid under strict sterile conditions, and perform the following tests: gross examination of appearance, viscosity, and color; a white blood cell count; the percentage of polymorphonuclear leukocytes; the glucose concentration of the aspirate; Gram’s stain; and culture. Tables have been published to differentiate the clinical presentation of pathogen and fluid from those associated with degenerative joint disease, inflammatory arthritis, and septic arthritis (51). Send all specimens to the laboratory promptly for immediate analysis. Culture the arthrocentesis fluid aerobically and anaerobically, and incubated in 5% to 10% CO₂ on chocolate agar plates if gonococcal arthritis is suspected. If tuberculous arthritis is a possibility, order a Ziehl-Neelsen stain and appropriate culture. Fungal infections may be viewed microscopically with potassium hydroxide preparations and cultured on Sabouraud’s medium. If the synovial fluid is centrifuged, the concentrated sediment often improves the yield of a Gram stain or other stain.

In the typical acute bacterial arthritis, the synovial fluid is purulent, being gray, yellow, or green, and usually opaque (Fig. 134.2) (91,97). The viscosity of the fluid is variable; however, the mucin clot is usually very friable. The synovial fluid white blood cell count is usually more than 50,000 cells/mm³ and is often over 100,000. Polymorphonuclear leukocytes constitute at least 75% of the cellular population and frequently make up more than 90%. Synovial fluid glucose concentration is usually lower than the blood glucose level. Frequently, the fasting blood minus synovial fluid glucose level is more than 50 mg/dl (67). In tuberculous and fungal arthritis, the findings are similar, except there is usually a higher proportion of mononuclear cells (30% to 50%). Look for the presence of crystals under polarized light to rule out acute gout or pseudogout in atypical arthritis.

**Figure 134.2.** Pus aspirated from a knee joint infected with *Staphylococcus aureus*.

Take cultures of the blood and other portals of entry. This may include any suspicious skin lesion or wound, the nasal pharynx, sputum, urine, and stool. Approximately 50% of patients with nongonococcal bacterial arthritis have a positive blood culture, whereas the frequency of positive synovial fluid cultures ranges from 25% to 97% (38). If the patient was treated with antibiotics before the synovial culture was obtained, the yield is much lower.

Various specialized diagnostic studies have been used to detect bacterial antigens (94), metabolites (11), and monoclonal antibodies (84) in the synovial fluid in cases of septic arthritis. These procedures are sometimes costly and in practice have had only limited application. Immunodiagnosis employs monoclonal antibodies in patients with culture-negative infections, especially those who have been previously treated with antibiotics. The method employs immunofluorescent staining of synovial fluid with commercial antibodies to *Staphylococcus aureus* or *Neisseria meningitidis*, and *Haemophilus influenzae* type b (38,111). If the antibody to a bacterial antigen is found, then the patient has been previously exposed and the immune response has been activated; however, the test does not differentiate between a recent exposure or a remote one. These tests have been shown to be positive in 75% of patients with *H. influenzae* infection (63).

Always take radiographs of the involved joint. The film may show evidence of pre-existing disease and may alert the physician to the possibility of a superimposed septic arthritis. Usually, however, the radiographs show soft-tissue swelling and synovial distention and little more. Later radiographs (1 to 2 weeks) may show osteopenia in the subchondral area or evidence of a coexisting osteomyelitis. Subluxation or dislocation of the joint may be seen early or late. It is more common in the hip of the infant and may be accompanied by exuberant new periosteal bone formation (67). Septic arthritis associated with subluxation of the glenohumeral joint has been documented in the adult (62). If a gas-forming organism (e.g., some gram-negative organisms and anaerobes) is the cause of septic arthritis, the radiograph may disclose gas in the joint and surrounding tissues (65). Late radiographic changes in untreated cases of septic arthritis include progressive joint narrowing and destruction. Fibrous or bony ankylosis may be the final result.

Postoperative hip infections are of particular interest because the appearance of the "classic" radiographic signs may be altered (54). In a series of proven hip infections after surgical treatment of hip fractures with internal fixation, Lewis and Norman found that periprosthetic edema was absent in 50% of patients. Joint space narrowing was the initial and most reliable radiographic sign and the appearance was recognized as early as 4 weeks after surgery. Later acetabular destruction superiorly in the weight-bearing area was often accompanied by subluxation. If septic arthritis is suspected in a prosthetic joint, radiographs should be taken to assess whether there is evidence of new periosteal bone formation, bone lysis, or loosening of the arthroplasty (88). This subject is discussed in more detail in Chapter 135.

Joint scintigraphy using technetium phosphate, gallium citrate, indium, or other radioisotopes is sometimes helpful in the diagnosis of difficult cases of septic arthritis (55-59). The scan may localize septic areas that are difficult to examine clinically and may help differentiate cellulitis from septic arthritis or osteomyelitis. Further localization of difficult joints (e.g., the sacroiliac or sternoclavicular joints) may also be afforded by plain or computed tomography (CT) (67).

Monoclonal antibodies can be labeled with technetium 99m to help detect infection. This test is 95% sensitive, but the specificity is lower at 85% because the test
cannot distinguish between infection and inflammation (3).

Magnetic resonance imaging (MRI) can show the presence of infection earlier than radiographs, because MRI is sensitive for detecting fluid in joints and is able to show abnormalities within 24 hours (13,49,50). MRI has low specificity because it cannot distinguish fluid from infectious, inflammatory, or hemorrhagic causes. MRI is useful in showing infections of the soft-tissue and bony involvement of the spine and pelvis or chronic osteomyelitis. It also shows marrow changes, contrast between bone and soft tissue, and anatomic detail. Generally, T1-weighted images show decreased signal intensity, whereas increased signal intensity is seen on T2-weighted imaging because of macroscop edema, ischemia, or exudation. Chronic cases show well-defined soft-tissue abnormalities, and thickened cortices, whereas an acute infection shows poorly defined soft-tissue planes, no cortical thickening, and poor distinction between normal and diseased marrow.

MRI with gadolinium enhances the visualization of osteomyelitis and the presence of an abscess. MRI is also useful in cases that may need surgical treatment, especially of the spine or pelvis. A study by Hovi et al. (43) found that persistent pathologic findings on MRI were seen in some patients despite normal C-reactive protein (CRP) levels and a low erythrocyte sedimentation rate (ESR). The investigators suggested that antimicrobial therapy continue even in the absence of clinical signs of infection and normal CRP levels and ESR if there are MRI abnormalities consistent with infection.

Rarely, a synovial biopsy is required to distinguish a case of infectious from noninfectious arthritis or to provide material for culture and histologic analysis in difficult, perplexing cases (30).

MICROBIOLOGY

Gonococcal arthritis caused by N. gonorrhoeae is the most common cause of septic arthritis in the healthy adult population younger than 40 years of age. It has been estimated that two to three cases of gonococcal arthritis are seen for every case of bacterial arthritis (24).

S. aureus continues to be the most common agent responsible for nongonococcal bacterial arthritis, appearing in about 60% of cases (15). In a series from Boston University Medical Center published between 1965 and 1982, S. aureus accounted for 40% of cases of nongonococcal bacterial arthritis (31). Various streptococcal species constituted 27% of infections. Recently, gram-negative bacillary septic arthritis has become more prevalent, constituting 23% of cases in the above-mentioned series. Diplococcus pneumoniae (6%) and S. epidermidis (4%) accounted for the remainder. In two other large series, staphylococcal infections played an even more prominent role. Staphylococci made up 77% (108 of 141, and 80 of 104 cases) of all bacteria isolated in nongonococcal septic arthritis in adults (62,74). These bacteria are showing increasing penicillin resistance (105), necessitating the use of alternative chemotherapeutic agents.

Streptococcal species, including S. pneumoniae (pneumococcus), almost always cause septic arthritis through hemogenous spread from the upper or lower respiratory tract or skin. Other rare sources of infection include (12-19,53). Gram-negative bone and joint infections (20-23) are less clear. In general, internists and pediatricians favor repeated aspiration of an infected joint; most surgeons favor surgical drainage (3,79,104,117). Whereas Pseudomomas aeruginosa and Serratia marcescens septic arthritis are usually associated with intravenous drug abuse, Escherichia coli and Proteus mirabilis infections often stem from urinary sepsis (28,80,116).

Many other gram-negative organisms have also been implicated in cases of septic arthritis (28,103).

Septic arthritis in neonates, infants, and children has a slightly different bacteriology. For the first few months of life, the neonate attains passive immunity from maternal antibodies. In this age group, the most common bacteria causing septic arthritis include gram-positive cocci (staphylococcal and b-streptococcal species) and gram-negative and gram-positive bacilli. These bacteria are often from invasive procedures such as intravenous catheters introduced in the hospital nursery. Gonococcal arthritis should always be kept in mind in this age group. Infants older than 6 months of age and children up to several years of age have an increased incidence of H. influenzae infections in addition to the common neonatal organisms. Frequently, septic arthritis due to H. influenzae is resistant to ampicillin. In children older than 2 years of age, S. aureus is the usual bacterial organism cultured; however, H. influenzae, streptococcal, gonococcal, and other organisms may be the cause (34,35,68,70). In older children, infection associated with a foreign body in the joint (e.g., the knee) should always be suspected.

Mycobacterial (typical and atypical) and fungal septic forms of arthritis are rare. In general, appropriate cultures should be made to exclude these agents, especially in the case of an immunocompromised host (33,66). The atypical mycobacteria, including Mycobacterium kansasii, Mycobacterium marinum, Mycobacterium intracellulare, and others, usually cause a monoarticular-pauciarticular arthritis of the hands or knees (21). Myotic septic arthritis may include infection with Spirorrhix schencki, Candida species, the maduromycoses, Cryptococcus neoformans, Coccidioides immitis, Blastomycoses dermatitidis, Aspergillus fumigatus, and others (41).

Viral-associated arthritis may occur during infection with any of the more common or uncommon viruses (98). It frequently appears with infection due to rubella, hepatitis B and alphavirus, and less commonly with infection due to mumps, adenovirus, herpesvirus, and enterovirus. Joint symptoms are transient, often polyarticular, and nondestructive. The etiology of the arthralgia or arthritis may be due to direct synovial invasion of the virus or to a virus-host interaction involving stimulation of the immune system (96).

Predisposing factors are the major etiology of nongonococcal bacterial arthritis, with the most important being total joint arthroplasty. The rate of infection following total joint arthroplasty of the hip and knee is 1% to 5%, with S. aureus being the most common cause (13,75).

Factors associated with hip infections include slow convalescence from an illness or surgery, urinary tract infection, failure of fixation of a hip fracture, and diabetes mellitus. Factors associated with knee joint infections include antibiotics given for wound infections, increased pain and limited motion, and rheumatoid arthritis (26). Sickle cell disease continues to be an important predisposing factor for pyarthrosis, especially due to salmonella. Human immunodeficiency virus (HIV) infection is becoming a more common predisposing factor, with S. aureus as the most common organism and the knee the most common site (63).

Postoperative infections after orthopedic procedures are usually due to one predominant organism. Gram-positive bacteria (i.e., S. aureus and S. epidermidis) comprised 80% to 85% of the organisms cultured (63,91). Gram-negative and multiple organisms occur less frequently. After joint replacement, staphylococcal infections take on a new significance (96,105). S. epidermidis infection becomes as common as S. aureus and appears to be more difficult to eradicate (105). In one large series of 137 infected total hip replacements, 68% of cultures grew gram-positive organisms. 18% grew gram-negative organisms, one hip was infected with multiple organisms, and 11% of cultures were sterile (results in two cases were not available) (45). Most authors agree that infection with gram-negative organisms or mixed organisms yield the worst results (14,44,65,105). This subject is discussed in greater detail in Chapter 135.

TREATMENT

Any suspicion of the diagnosis of septic arthritis demands an immediate thorough workup, including history, physical examination, appropriate blood work, radiography, joint aspiration with Gram's stain and culture, and an intense search for a primary infective focus.

The principles of treatment of septic arthritis include the following:

- Sterilize the joint by providing adequate drainage and appropriate antibiotics in sufficient dosages to kill the pathogen.
- Prevent the occurrence of deformity.
- Sterilize the joint by providing adequate drainage and appropriate antibiotics in sufficient dosages to kill the pathogen.
- Fully rehabilitate the joint and limb (37).

ASPIRATION VERSUS SURGICAL DRAINAGE VERSUS ARTHROSCOPY

Perhaps the most controversial aspect in the treatment of septic arthritis is the method of drainage. All agree that adequate drainage is of paramount importance. It mitigates the ongoing degradation of the cartilage ground substance by the enzymes of the polymorphonuclear leukocytes and lysosomes within the synovium (18,16,19). The debate centers around the method of drainage—in other words, whether repeated aspiration or surgical drainage is indicated.

Whereas virtually all physicians believe that septic arthritis of the hip and other less accessible joints require surgical drainage, the method of treatment in other joints is less clear. In general, internists and pediatricians favor repeated aspiration of an infected joint; most surgeons favor surgical drainage (6,27,31,38,52,57,74,79,91). Arthroscopy is the next best modality of choice for the knee, and when the surgeon is experienced, it is also the method of choice for the shoulder, elbow, wrist, and ankle (23,43). Indeed, Paterson has stated, “It is suggested that aspiration has no place in the treatment of suppurative arthritis of the hip, and it is not considered a safe method for any other joint” (79). However, there have been no randomized, prospective studies to document the superiority of one form of treatment over the other. Several retrospective studies (79,107) have compared the two methods of treatment and concluded that patients undergoing needle aspiration did better than those undergoing surgical drainage and debridement. However, the controversy has not been settled. Other issues are also involved, for example, consider how difficult it is to convince a pleading, crying child with septic arthritis that he or she must undergo aspiration once (or more) per day. See Chapter 176 for more details about pyarthrosis in children.
Aspiration

If aspiration is the chosen treatment, aspirate the joint frequently enough to prevent the stagnation and loculation of pus, initially, aspirate once or twice each day (28:31.91). Careful sterile technique is mandatory.

- Use a large-bore (at least an 18-gauge) needle for larger joints. Culture the aspirate every 1 to 2 days after antibiotic treatment has commenced to assess the efficacy of therapy. Continue aspirations until little exudate is retrieved and repeat joint fluid cultures are negative.
- Monitor the clinical status closely. It is sometimes useful to lavage the joint with saline after the aspiration to wash the debris and chondrolytic enzymes from the joint.
- The specific location of the needle insertion for aspiration is not important, as long as adequate drainage is attained and the joint and important structures around it (i.e., vessels, nerves, tendons) are not injured (27:77.91).
- We find it easiest to aspirate the shoulder either anteriorly or posteriorly. In the anterior approach, direct the needle posteriorly, superiorly, and laterally from a point slightly inferior and lateral to the acromion process. This maneuver is often facilitated by external rotation of the shoulder. For the posterior approach, enter the joint 1.5 inches (3.75 cm) inferior and medial to the acromial angle.
- Approach the elbow joint posterolaterally, just below the midpoint connecting the lateral epicondyle and the lateral edge of the olecranon. Keep the elbow flexed 90° during the aspiration.
- Approach the wrist dorsally. This provides excellent access while avoiding many of the critical structures in the area.
- Enter the finger joints through a posteroanterior or posteroanterior stab, just volar to the extensor mechanism using a smaller bore needle.
- The synovial lining of the thumb is more difficult because of the large number of tendons, nerves, and vessels passing in the vicinity. It is approached most safely by flexing the thumb across the palm and directing the needle at the base of the first metacarpal bone to the radial artery and anatomical snuff box, aiming for the fourth metacarpal base.
- The hip joint is one of the most difficult to aspirate. All physicians involved in the treatment of pyarthrosis must know the proper technique. Aspiration of the hip is best performed in the radiology suite or operating room, where good radiographic imaging with fluoroscopy is available. Place the patient in the supine position on a radiolucent table. In the anterior approach, extend and externally rotate the hip. Introduce the needle 1 inch (2.5 cm) below the anterolateral iliac spine and 1 inch (2.5 cm) lateral to the palpable pulsations of the femoral artery. Direct the needle into the joint posteromedially at a 60° angle. For the lateral approach to the hip, position the hip in extension and internal rotation. Identify the greater trochanter. Direct the aspiration needle along the anterior portion of the greater trochanter, parallel to the femoral neck, then medi ally and cephalad toward the middle of the inguinal ligament.
- The knee joint is the easiest joint to aspirate because it is superficial and contains the largest synovial cavity in the body. With the patient in the supine position and the knee fully extended, insert the needle from a midlateral or midmedial parapatellar approach and direct it posteriorly and inferior to the patella. Take care not to scratch or scuff the articular surfaces.

Surgical Drainage

Although the indications for surgical drainage of various joints remain controversial, there is general agreement that deeper joints such as the hip and sacroiliac joints, which are less accessible to aspiration, should be treated surgically. Another indication for surgical drainage is thick purulence or loculations within the joint. Also, drain surgically any joint that does not respond to repeated aspirations and appropriate systemic bactericidal antibiotics within 48 hours.

Surgical drainage of a septic hip joint is almost always recommended in the child because of the difficulty in aspiration of this deeply seated joint, the risk of inadvertent damage to the joint surface during the procedure, and the risk of avascular necrosis to the head of the femur. The avascular necrosis of the head of the femur may result from compromise of the retinacular vessels caused by increased intracapsular pressure (35:47.79).

If open surgical drainage of a septic joint is indicated, perform the operation promptly. The aims of surgery are to debride the joint thoroughly; excise all dead, infected, nonviable tissue; and assess the articular surface with respect to the possible need for future reconstructive procedures. Some investigators believe that a concomitant synovectomy is indicated, especially if there has been any delay in diagnosis or a poor response to antibiotic treatment and drainage by closed means (25:112). In one study, severe joint late destruction in cases of septic arthritis involving the knee joint but not the hip (112). At a minimum, the joint should be thoroughly debrided of all nonviable tissue. During arthroscopy, always take appropriate specimens for microbiologic and pathologic studies.

Choose a surgical approach that allows wide drainage and complete inspection of the joint. We believe that the joint should not be left open to the environment for fear of colonization of the dressings (and joint) with other organisms. We close the debrided joint over suction tubes, which are removed after several days, depending on the patient’s clinical response and the amount and type of drainage.

Tube-suction Drainage

- Occasionally, suction drainage has been combined with an irrigation system, particularly when a great deal of thick, purulent material has been excised (16:59).
- Depending on whether the joint is involved, establish a suitably sized inflow catheter on one side of the joint, and one or two larger bore outflow catheters on the opposite side of the joint. (For example, a central venous pressure tubing or small Hemovac drain may be used for inflow irrigation of the knee joint, and a larger bore Hemovac drain may be used for outflow.) Place the drains far enough apart so that distention of the joint and circulation of the fluid will be accomplished.
- Leave the effusion entirely closed, and secure all tubing joints with adhesive tape.
- A physiologic saline solution may be infused at a rate sufficient to provide a constant outflow. Antibiotics need not be added to the irrigant because sufficient joint levels are attained with systemic antibiotics (73:98.06, 100:101 and 102).
- Leave the irrigation tubes in place for 2 to 3 days and then remove them. Leave the effluent tubes in place for approximately 24 hours after the inflow tubes are removed.
- These time periods have been selected because of experimental evidence that has demonstrated changes in the articular cartilage glycosaminoglycan staining after 3 days of constant saline irrigation (50:); these changes reflect deprivation of the nutrients in the synovial fluid that normally bathes the articular cartilage. Furthermore, if drains are left in much longer than several days, they may serve as a portal of entry for bacteria and may contribute to the formation of a synovial fistula (59:115).

Arthroscopic debridement has been used in conjunction with systemic antibiotics to debride infected joints, most notably the knee. Although most of the reported series are small, this method appears to allow adequate drainage and visualization of the joint with minimal morbidity (23:47.48).

Approaches for Specific Joints

- Specific surgical approaches for open arthrotomy include the standard approaches outlined in Chapter 1, Chapter 2 and Chapter 3. If the joint is to be left open, then dependent drainage can be facilitated by the surgical approach selected and appropriate postoperative positioning techniques. We routinely close arthrocentesis incisions and use suction (with or without irrigation), so the actual approach may be of less importance because joint dependency is not necessary.
- The shoulder joint may be decompressed either anteriorly or posteriorly; we usually select the anterior approach. We use a deltopectoral approach and identify the shoulder joint beneath the subscapularis muscle, which is reflected medially, allowing a cuff of tendon to remain on the lesser tuberosity for closure.
- The elbow joint is most easily debrided posterolaterally through an oblique incision between the extensor carpi ulnaris and anconeus muscles. If a posteroanterior approach is selected, identify and protect the ulnar nerve.
- Approach the wrist joint and carpus dorsally, with the forearm pronated. Make a central incision and enter the wrist joint between the third (extensor pollicis longus) and fourth (extensor digitorum communis) compartments. Reconstruct the extensor retinaculum before closure.
- Use a midlateral or midlateral approach for the fingers. Avoid injury to the digital nerves and vessels.
- Arthrotomy of the hip joint may be performed through a number of different approaches. We prefer the standard anterior iliofemoral approach in children and the posteroanterior, gluteus maximus–splitting approach in adults. If the hip joint is to be left open, we recommend the posteroanterior approach because it allows dependent drainage with the patient supine. A child may be placed in the prone position after an iliofemoral approach.
- For the knee joint, the anteromedial or posteroanterior parapatellar approach allows excellent surgical decompression and visualization of the knee joint. The anteromedial approach is most often used. Use the posteroanterior approach just posterior to the medial collateral ligament if dependent drainage is required.
- The ankle joint may be exposed by numerous approaches (anteromedial, anterolateral, posteroanterior, or posteroanterior). We use the anterolateral exposure lateral to the extensor digitorum longus) or posteroanterior exposure (between the tibia and the Achilles tendon) most often. In the posteroanterior approach, identify and protect the sural nerve. This approach allows dependent drainage in the supine position if the wound is left open.
**ANTIBIOTICS**

The proper selection of antibiotic therapy is an integral part of the treatment of septic arthritis (29,38,41,52,70,73) (see Chapter 132). The immediate Gram stain of the synovial fluid may identify specific microorganisms, which will determine the choice of antibiotics. If no organisms are seen on Gram's stain but pus cells are identified in the aspirate, administer antibiotics according to the "best guess principle," as described later. Continue them until the results of the synovial aspirate and blood cultures become available, which is usually within 24 to 48 hours.

Administer antibiotics intravenously. Bacterioidal antibiotics are generally preferred over bacteriostatic agents. Intra-articular injection of antibiotic is not necessary because adequate levels are achieved in synovium and bone with parenteral use; also, a chemical synovitis may result from direct intra-articular inoculation (31,71,73,98,99,100,101 and 102). In difficult cases, the blood and synovial fluid may be monitored to ensure that antibiotic levels are above the minimal inhibitory concentration for a specific microorganism.

There is no general agreement as to how long to treat a patient with septic arthritis with antibiotics. In general, we treat with parenteral antibiotics until systemic toxicity and local swelling are under control. We monitor the white blood cell count and the ESR in peripheral blood, and perform repeated synovial fluid aspirations in patients with needle drainage. We culture the aspirate every 1 to 3 days and perform a Gram stain. A glucose concentration, white blood cell counts, and polymorphonuclear leukocyte counts may be performed as well. We continue antibiotics orally an additional 2 to 3 weeks after the course of parenteral antibiotics. This may be done on an outpatient basis with close supervision. Longer courses are recommended for those with concurrent osteomyelitis, for gram-negative infections, multiple microorganisms, or in the immunocompromised patient. We frequently confer with our infectious disease colleagues, especially in more complex situations.

If gram-positive cocci are noted on the initial Gram stain, staphylococcal or streptococcal species are the usual microorganism. We use a semisynthetic, penicillinase-resistant penicillin (e.g., nafcillin, oxacillin, cloxacillin, 8 to 12 g/day, given every 4 to 6 hours in adults; 150 to 200 mg/kg daily, given in four to six divided doses in children) until cultures are available. Alternate choices include a cephalosporin (e.g., cefazolin, 1 to 2 g intravenously every 6 hours in adults; 100 to 200 mg/kg daily in children), or vancomycin (2 g/day in divided doses in adults; 40 mg/kg daily in two divided doses in children). We continue the above-mentioned regimen if penicillinase-producing staphylococci are cultured. In penicillin-sensitive cases (e.g., some S. aureus and streptococcal infections), we switch to penicillin G (10 million units, given in four divided doses in adults, given in six divided doses in children). Vancomycin may be substituted in patients who are allergic to penicillin.

Gram-negative cocci in a septic joint in an adult usually signify gonococcal infection. We recommend the use of parenteral penicillin therapy (penicillin G, 10 million units daily, in four divided doses). The patient can be switched to oral penicillin therapy when signs and symptoms abate, for a 2-week course. Spectinomycin is recommended in patients with penicillin-producing gonococcal infection (69). Third-generation cephalosporins can be extremely effective, and long-acting agents such as ceftriaxone are being used with increasing frequency.

Gram-negative coccal organisms in an infant's or young child's synovial aspirate may signify H. influenzae infection. Whereas we used to give a combination of ampicillin and chloramphenicol, these drugs are presently less used because of ampicillin resistance and the very close monitoring of serum concentrations and side effects. In the hospital, we use cefotaxime, or a second-generation cephalosporin (100 mg/kg daily, given every 8 hours). Other alternatives include cefotaxime and ceftriaxone. The clinical response is monitored closely, and a final choice is made when cultures are available.

Gram-negative bacilli seen on Gram's stain of the joint aspirate require immediate treatment and close observation. Look for infection of the urinary tract and bilateral tricus, for generalized debilitating disease, and for the possibility of drug abuse (28,90,103,104,116). We use tobramycin (5 mg/kg daily, given in three divided doses), gentamicin (same dose), or amikacin (15 mg/kg daily) until the cultures are returned. Ticarcillin (300 mg/kg daily given every 4 to 6 hours) is frequently prescribed by our infectious disease colleagues in addition to one of the above-mentioned drugs, especially for Pseudomonas infections. If aminoglycosides are used, monitor renal and vestibuloauditory function, at least on a weekly basis. Obtain antibiotic peak and trough blood levels in the first few days and repeat later if clinical response is not appropriate, or if aminoglycosides are used.

If the Gram stain does not show the presence of any bacteria, a "best guess" must be made until the cultures return. The physician must consider the patient's age, associated disease, and immunocompetence. In the neonate, the most common bacteria causing septic arthritis include gram-positive cocci (staphylococcal and bac- negative cocci) and gram-negative rods (P. aeruginosa). In the immunocompromised host, we generally use cefotaxime, a second-generation cephalosporin (100 mg/kg daily, given every 8 hours). Other approaches include cefotaxime and ceftriaxone. In the immunocompromised patient, a cephalosporin or an aminopenicillin may be used. In the immunocompromised host, we combine an anti-staphylococcal agent with tobramycin, gentamicin, or amikacin. A consultation with an infectious diseases specialist can be very helpful.

In adults, ciprofloxacin, a fluoroquinolone antibiotic, may prove useful for the continuation of oral therapy, after a course of intravenous antibiotics with another drug. Ciprofloxacin is bactericidal against most gram-negative aerobic bacteria (including P. aeruginosa), some strains of S. aureus and S. epidermidis, and enterococcus. Ciprofloxacin has poor activity against anaerobes. Perform sensitivity testing. This drug is a useful adjunct because it requires oral administration only twice per day. It is not recommended for children. Absorption of ciprofloxacin is markedly decreased by aluminum- and magnesium-containing antacids. Ciprofloxacin administration also increases the serum theophylline level in patients taking these drugs simultaneously. Monitor serum theophylline levels closely.

In the treatment of tuberculous septic arthritis (41), combination therapy is most commonly prescribed, including two or more of the following: isoniazid (300 mg/day in adults, 5 mg/kg daily in children), ethambutol (15 mg/kg daily in children, 15-25 mg/kg daily in adults), rifampin (600 mg/day in adults; 10 mg/kg daily in children). Pyridoxine is given to prevent neuritis if isoniazid is used. Liver function should be closely monitored with isoniazid, and one should be aware of the lupus pernio associated with it. Thrombocytopenia, hepatitis, and flulike syndromes may be associated with the use of rifampin, and visual disturbances may be associated with ethambutol. Continue therapy for at least 18 months. Other drugs that may be useful include streptomycin and aminosalicylic acid.

Antifungal chemotherapy with intravenous amphotericin B (0.6 to 1.0 mg/kg daily) must be performed with great caution because of the toxicity of this drug. Monitor renal, hematologic, gastrointestinal, and other side effects closely.

**REHABILITATION**

The concept of early joint motion in the treatment of septic arthritis is not a new one. Before the use of antibiotics, Willems in 1919 advocated surgical débridement and early active motion for septic joints (116). This concept was further put to use by Ballard et al. (6), who combined arthrolysis, systemic antibiotics, and early, active range-of-motion exercises in the treatment of septic arthritis of the knee. They demonstrated an 82% fair or good result rate despite a difficult population composed primarily of prior treatment failures. Perhaps the most elegant experimental study was performed by Saltzer’s group (95). Using a model of staphylococcal septic arthritis

- Approach the small joints in the foot and toes dorsally (deltus) or medially or medially (toes), through exposures similar to those used in the hand.
- In each case, thoroughly irrigate, debride, inspect, and loosely close the joint over suction tubes. Irrigation tubes may be added if the purulent material is thick. Close skin and subcutaneous tissues loosely. If the infection is particularly worrisome (loculated with thick pus, severe joint destruction), leave the joint open to granulate. Change dressings three to four times per day for open wounds, using hydrogen peroxide or another antiseptic solution.
- After surgery, we splint septic joints in the functional position and begin active assisted and gentle passive range-of-motion exercises when the inflammatory response subsides, usually after 24 to 48 hours. We have not used postoperative continuous passive motion, but experimental evidence suggests that this modality may prove useful in maintaining joint range of motion and minimizing loss of cartilage glycosaminoglycan (53). Certainly, prolonged immobilization appears to be contraindicated because it leads to intra-articular adhesions, more cartilage destruction, stiffness, atrophy, and poor rehabilitation.
- With respect to lower extremity joints, use protected weight bearing until inflammation has ceased, range of motion is pain free, and rehabilitation is well under way. In general, do not perform extensive bony or soft-tissue reconstructive procedures during the acute phase of septic arthritis; postpone these procedures until the infection has resolved and the joint has been fully rehabilitated.
of the rabbit knee, they combined arthrotomy and antibiotic treatment with either plaster immobilization of the knee joint, cage activity, or continuous passive motion (CPM) on a specially designed machine. The CPM group fared the best, showing decreased cartilage ground substance losses compared with the other treatment methods. Our current treatment protocol emphasizes proper splintage during the early stages of treatment, with the institution of active assisted and gentle passive range-of-motion exercises after 24 to 48 hours, when the inflammation and pain subside. We delay weight bearing on septic joints of the lower extremity until range of motion and strength are virtually normal.

PROGNOSIS AND COMPLICATIONS

Denis Paterson of the Adelaide Children's Hospital has emphasized that “every hour that an acute suppurative process continues within a joint is of urgent significance to prognosis” (79). Lloyd-Roberts agreed that Paterson did “not exaggerate the sense of urgency required of us when confronted by either the certainty, probability or even the possibility of this affection” (67).

Numerous studies have demonstrated a negative correlation between the length of time from onset of symptoms to documentation of a sterile joint and the quality of the outcome (7,29,31,39,58). Other factors associated with a poor outcome include immunodeficiency in the host (e.g., malignancy, rheumatoid arthritis, or prematurity in neonates), concomitant osteomyelitis, infection involving the hip joint or any prosthetic joint, the presence of positive blood cultures, and infection with S. aureus or multiple organisms, especially anaerobes or gram-negative rods (46), symptoms greater than 1 week before treatment, involvement of more than four joints, and positive cultures with repeat aspiration after 7 days of antibiotic treatment (107). In general, gonococcal arthritis has a much better prognosis if treatment is instituted promptly (6,17,24,42,51,76,109).

Complications associated with septic arthritis include death, variable destruction of the joint with residual joint stiffness and functional limitation, subluxation and dislocation, avascular necrosis, local growth disturbance (Fig. 134.3), osteomyelitis, and postinfection synovitis (6,7,21,29,39,58,72,79,92,106).

The incidence of death from septic arthritis has ranged from 8% to 15% in three series published since 1975 (29,39,92). Mortality rates are highest in people with one or more of the poor outcome factors mentioned earlier.

The consequences of septic arthritis of a joint, especially the hip, in a growing child can be disastrous (7,21,57,58,72,80,106). Avascular necrosis, sequestration and absorption of the femoral capital epiphysis, chondrolysis of the articular cartilage, destruction of the epiphyseal plate with growth disturbance or arrest, and subluxation or dislocation of the epiphysis or entire hip joint can occur. These complications have a profound effect on a child of any age and may herald a long course of repeated reconstructive surgeries. In the adult, degenerative arthritis with fibrous or bony ankylosis may be the result. These complications may occur in virtually any septic joint but are most profound in the hip (Fig. 134.4).

Recurrent synovitis may persist despite the eradication of microorganisms from the joint. This complication is most common after intra-articular antibiotic injection (6). Nonsteroidal anti-inflammatory drugs may aid in the treatment of this puzzling residuum.

Overall, the fact that septic arthritis has a favorable outcome in approximately 50% to 80% of cases (29,39,92) emphasizes the need for a heightened index of suspicion of this disease and the immediate institution of appropriate diagnostic and treatment procedures.

CHAPTER 135

MANAGEMENT OF INFECTED IMPLANTS

Kevin L. Garvin, Matthew A. Mormino, and Theresa M. McElnay

Infection has been a major nemesis for orthopaedic surgeons for as long as medical history has been recorded. Its frequency and severity have lessened considerably, but occasionally it is still responsible for compromising an otherwise good outcome for the patient. The recent emergence of bacteria that are resistant to antibiotics are of increasing concern. The purpose of this chapter is to present the principles of treatment for infection involving prosthetic joints and internal fixation devices for long bones.

PATHOGENESIS AND PATHOPHYSIOLOGY

The initial event of infection occurs when bacteria successfully lodge on or near the implanted prosthesis. The easiest and most common access for bacteria is the surgical wound. They flourish in this environment because trauma to the tissues by the surgery, causes some tissue necrosis is due to direct trauma, compromises the blood flow to the tissues and results in hematoma formation. The presence of the large foreign body provides a surface for the bacteria to adhere to.

The other routes bacteria may take to reach the area are hematogenous seeding and contiguous spreading from adjacent areas of infection. The hematogenous spread of bacteria to a prosthetic joint has been associated with chronic skin lesions, dental manipulation, urinary infection, diabetes, and other chronic diseases. One of several scenarios may take place once the bacteria have gained entry to the area. Bacteria may be destroyed by the host; live in symbiosis with the host, or flourish, causing local infection, host sepsis, and even death.

The body's first response to bacterial invasion is an acute inflammatory reaction. A myriad of components are involved in this process, including polymorphonuclear cells, chemotactic factors, and the immune system. Leukocyte diapedesis occurs, followed by infiltration of polymorphonuclear cells to the area. The process in which polymorphonuclear cells are attracted to the area by chemical substances is known as chemotaxis. Boyden originally discovered that chemotaxis occurred if serum was incubated with precipitates of antigens of antibiotics.

The immune system is composed of cell-mediated and humoral components. Both cell-mediated and humoral responses are activated to fight bacterial infections. Once the polymorphonuclear cells attack bacteria, some may be damaged, thus releasing additional chemotactic molecules that attract even larger numbers of polymorphonuclear cells. When the polymorphonuclear cells are in proximity to the bacteria, the particles are phagocytosed. For phagocytosis to occur, opsonins or components in the serum must coat the bacteria, making them more attractive for the macrophage.

Elderly patients, the population most commonly managed with joint replacement, may be particularly susceptible to infection because their immune systems are compromised. With increasing age, the immune becomes less competent. These changes include atrophy of the thymus, a decreased ability to mount a delayed-type hypersensitivity to various stimuli, and a generalized decreased ability of lymphocytes response to respond to foreign stimuli.

The nonspecific immune response can be affected not only by activation of the complement system but also by certain medications. Nonsteroidal anti-inflammatory agents, steroids, and aspirin are common medications that suppress the immune response.

Although the list of potential pathogens is virtually limitless, coagulase-negative staphylococci and Staphylococcus aureus dominate the list of pathogens. In a combined study from the Mayo Clinic and The Hospital for Special Surgery, 97 pathogens were isolated from 76 patients who had periprosthetic hip infections. Staphylococcus epidermidis and S. aureus were identified 36 and 18 times, respectively, accounting for more than one half of the pathogens. Streptococcus viridans, group-D Streptococcus or Enterococcus, and beta-hemolytic serogroups, also gram-positive organisms, accounted for an additional 14 pathogens. These gram-positive organisms as well as gram-positive anaerobic bacteria accounted for a total of 76% of the 97 pathogens. Gram-negative aerobic and facultative organisms accounted for 11% of the 97 organisms and included Escherichia coli, Proteus mirabilis, Pseudomonas aeruginosa, Salmonella choleraesuis, and Campylobacter intestinalis.

Table 135.1. Common Bacteria Involved in Periprosthetic Infections

Other gram-negative organisms that are commonly reported but were not found in this study are Klebsiella, Serratia, Acinetobacter species, and other Pseudomonas species. Finally, anaerobic bacteria were identified 12 times (12%) in the study and included Propionibacterium acnes, Peptococcus asaccharides, Peptococcus magnus, Peptostreptococcus microphore, and Clostridium bifermmentans. Other anaerobic bacteria that are commonly reported but were not found in this study are...
soon after the remote infection or as late as 2 or even several years after the hip replacement.

A history of prolonged drainage after the operation in a patient who has persistent pain can be very helpful in establishing the correct diagnosis. Fever is not a common presenting complaint, because only 5% of patients with an infected joint replacement have a temperature of 37.8°C or more (18). A history of the joint replacement having “never been right” raises the clinical suspicion of infection. After knee replacement, joint stiffness may be present, and although it is not diagnostic, this symptom raises the suspicion of infection (42).

Laboratory tests that are helpful in establishing the diagnosis of an infected implant include a complete blood cell count with differential, determination of the erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP). Of these tests, the CRP may be the most useful for evaluating and monitoring the patient’s response to therapy. After surgery, the CRP rises with a peak usually on the second or third day, but by 3 weeks, it is usually back to normal (54).

Sanzon and Carlson (52) examined a series of 23 patients with proven deep infections of hip replacements and found that the CRP was elevated (greater than 20 ug/L) in 19 patients. By comparison, 7 of the patients had an ESR of 20 mm/h or less. The CRP and the ESR were not elevated in only one of the 23 patients. The investigators also report that infection should be suspected if an elevated CRP has been recorded on several occasions (52).

Begin imaging studies with conventional radiographs, which may show radiolucent lines, focal osteolysis, or periosteal bone formation, which suggest infection. Unfortunately, the presence of periprosthetic lucencies is not specific for nor most commonly the result of infection. Mechanical loosening and foreign body histiocytic reaction are more common causes of lucencies and osteolysis.

Bone destruction and irregular periosteal reaction are uncommon manifestations but are strongly suggestive of an infected joint prosthesis (3). Typically, radiographs of infected prostheses are normal, show only a joint effusion, mimic mechanical loosening, or resemble aggressive granulomatosis. Unfortunately, the absence of any findings does not rule out the presence of an infection. Investigate further if infection is suspected clinically.

Nuclear medicine imaging can be extremely valuable in diagnosing periprosthetic infections. In patients without prostheses or other complicating factors, a three-phase bone scan using technetium-99m methylene diphosphonate (Tc-99m MDP) is highly sensitive and specific for osteomyelitis. In evaluation of suspected periprosthetic infections, however, bone scans retain their sensitivity but become nonspecific.

Increased uptake may occur normally with aseptic loosening or with infection (15,50,58). If abnormal increased uptake is present in the clinical setting of a painful prosthesis, perform leukocyte scintigraphy (LS), which is the preferred nuclear imaging method for identifying infected prostheses. LS involves labeling a patient’s white blood cells (WBCs) with radioisotopes (Indium-111 or Tc-99m complexed to hexamethyl propyleneamine oxide), reinjecting the WBCs, and then imaging the patient approximately 24 hours later. Especially when correlated with bone scans, indium leukocyte scintigraphy has a sensitivity of about 90% and specificity of about 85% for periprosthetic infections (43,49). Major drawbacks to the routine use of LS are the extensive time, labor, and cost of the technique.

Ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) have traditionally played a very limited role in the evaluation of patients with suspected deep infections. MRI is extremely useful in evaluating bone and soft-tissue infections of the spine and appendicular skeleton of patients without orthopaedic devices. Its use is limited, however, when metallic implants are present because of localized signal loss. CT is also hampered by artifact caused by the metal prosthesis and is less sensitive to musculoskeletal infections when compared with MRI.

If clinical or radiographic evidence suggests that an infection is present, the next step in the diagnostic workup is aspiration of the joint. Positive culture results confirm the diagnosis of infection as well as identify the organism and thus direct the course of treatment.

It is important to use joint aspiration selectively and understand its limitations. Barrack and Harris (3) reviewed the results of routine aspiration before 270 consecutive revision operations of the hip. An infection was identified at surgery in six hips, four of which had been successfully aspirated. In the other two hips, aspiration failed to yield any fluid. Thirty-two (13%) of the 254 patients who did not have an infection but had been successfully aspirated had a false-positive result on culture of the aspirated fluid (3).

Overall, Hambien reports that only about 50% of aspirations from infected joint replacements are positive (29). This finding emphasizes the importance of hip aspiration for patients whose history suggests infection or for those with radiographs showing focal osteolysis, aggressive nonfocal osteolysis, or periostitis, but not for all patients whose hips are scheduled for revision surgery.

INFECTED TOTAL HIP ARTHROPLASTY

CLASSIFICATION

In 1975, Coventry described the most widely accepted classification of periprosthetic infections of the hip (13) (Table 135.2). According to this system, stage I infections are acute, fulminating infections that develop within 3 months after the operation. They are clinically apparent wound infections or infections of hematomas that have progressed to deep infections. Stage II infections have never had a pain-free interval after the operation. A timetable for how late the infection may be diagnosed has not been well established, but the range for the diagnosis is 3 months to approximately 2 years after surgery.

Stage III infections are frequently hematogenous. The hip may function very well after the operation, but later, the patient has increasing symptoms of pain and impaired function. The symptoms may be associated with a previous infection remote to the hip joint (respiratory, dental, urinary tract, or skin lesion) and may develop soon after the remote infection or as late as 2 or even several years after the hip replacement.

INFECTED TOTAL HIP ARTHROPLASTY

CLASSIFICATION

In 1975, Coventry described the most widely accepted classification of periprosthetic infections of the hip (13) (Table 135.2). According to this system, stage I infections are acute, fulminating infections that develop within 3 months after the operation. They are clinically apparent wound infections or infections of hematomas that have progressed to deep infections. Stage II infections have never had a pain-free interval after the operation. A timetable for how late the infection may be diagnosed has not been well established, but the range for the diagnosis is 3 months to approximately 2 years after surgery.

Stage III infections are frequently hematogenous. The hip may function very well after the operation, but later, the patient has increasing symptoms of pain and impaired function. The symptoms may be associated with a previous infection remote to the hip joint (respiratory, dental, urinary tract, or skin lesion) and may develop soon after the remote infection or as late as 2 or even several years after the hip replacement.
The generally accepted criteria for a direct-exchange (one-stage) arthroplasty include the presence of a pathogen that is very sensitive to antibiotics. These include Staphylococcus and Streptococcus—and some antibiotic-sensitive gram-negative bacteria. The host should be healthy with few or none of the risk factors for infection (which include rheumatoid arthritis, diabetes, chronic skin lesions, and obesity). The joint to be operated on must have adequate bone and soft tissues to support the prosthesis. A preoperative bone scan or magnetic resonance imaging may be helpful in determining the bone stock available for revision surgery. The prosthetic components should be well fixed. The patient should be well mobilized, and the infection should be controlled with appropriate antibiotics for at least 4 weeks. This may be followed by implantation of a new prosthesis after the patient has been free of infection. Once the surgical procedure is completed, initiate parenteral antibiotic therapy to treat any microscopically retained bacteria and modify as necessary on the basis of culture results. Guidelines have been suggested for initial component retention in infected prosthesis and include:

- Use the previous surgical skin incision, and if necessary, excise it to remove any adjacent scar tissue. Dissect down to the prosthesis using the same surgical approach used for the initial surgery. This minimizes additional unnecessary bone and soft-tissue devitalization and permits removal of any previously placed deep nonremovable sutures that may be a nidus for infection.
- Obtain several tissue cultures from the pseudocapsular and intra-articular regions of the hip joint during debridement.
- Completely expose the prosthesis–bone or cement–bone interfaces to remove any granulation tissue or extension of the purulent process. Removal and exchange of the polyethylene liner of the acetabular component is particularly important because it allows more complete debridement of the metal shell–polyethylene interface.
- Irrigate the area extensively and close the wound in layers over deep drains.

Once the surgical procedure is completed, initiate parenteral antibiotic therapy to treat any microscopically retained bacteria and modify as necessary on the basis of culture results. Guidelines have been suggested for initial component retention in infected prosthesis and include:

- a short (less than 3- to 4-week) duration of symptoms
- a culture showing gram-positive organisms that are sensitive to antibiotics
- no loosening of the prosthesis
- an absence of excessive scar tissue from previous operative procedures

Gustilo and Tsukayama (28) reported the results after retention of the components, debridement, and treatment with antibiotics in 41 patients. Of the 35 patients who had had an early postoperative infection, 26 (74%) had a successful result, compared with only three of the six patients who had had an acute hematogenous infection. These authors suggest that early intensive debridement can be successful in carefully selected patients.

**ONE-STAGE REIMPLANTATION VERSUS TWO-STAGE REIMPLANTATION**

Although most surgeons agree that removal of hardware is necessary for adequate treatment of a deep infection with a compromised prosthesis, issues regarding reimplantation are less clear. Reimplantation can be performed after debridement and removal of the components, and appropriate antibiotics for 4 to 6 weeks. This may be followed by implantation of a new prosthesis after the patient has been free of infection.
deep infection persisted, three had had a sinus tract before the revision and a sinus tract reappeared within 3 months of the revision surgery. In three patients, the radiologic evidence of the persistence of infection first became obvious at the junction of the old and new cement within the medullary canal. The author concluded that adequate debridement and removal of all of the cement is essential. The use of antibiotic-impregnated cement cannot be advocated to the exclusion of all other aspects of revision (51).

If a one-stage procedure or direct exchange is chosen, it is recommended that antibiotics be added to the cement at the time of the reimplantation (23). The infecting organisms must be sensitive to the antibiotic used. It must be stable when it is exposed to heat so that its efficacy is not degraded by the polymerization of the cement. Geometric dilution of the powdered antibiotic and cement, or mixing equal amounts until all of the antibiotic powder and cement are mixed, ensured even distribution of the antibiotic, allowing for high levels of the antibiotic and adequate strength of the acrylic cement.

The advantages of direct-exchange arthroplasty include fewer operations, lower cost, and less inconveniency to the patient. The risks and consequences, if the technique is unsuccessful, however, are substantial and include sepsis, disarticulation at the hip, and operative mortality. Buchholtz et al. (19) reported 13 deaths (1.6%) as a result of 796 operations performed for the treatment of deep infection after prosthetic replacement.

Two-stage reimplantation is most commonly used for patients who have a deep periprosthetic infection of the hip. Reimplantation is performed after the patient has received 4 to 6 weeks of parenteral therapy with antibiotics, but it is often delayed for several weeks after completion of antibiotic treatment as well. Reports have shown that, for patients who have a deep infection of the hip, a two-stage reimplantation results in the highest rate of success, and most surgeons believe that two-stage reimplantation is the procedure of choice (21,22).

The exact timing of the reimplantation varies from center to center, but if the operative site has been treated appropriately during the first procedure, it is rare that the reimplantation cannot be performed after 6 weeks. In the time of reimplantation, the tissues are redebridged and specimens are sent for histopathologic analysis and culture. If the histopathologic analysis (frozen section) is positive (more than 5 polymorphonuclear neutrophils per high power field [PMN/HPF]), the surgeon may elect to postpone joint reimplantation in favor of a second debridement. It is critical to work with an experienced pathologist and have experience treating infected joints. The use of antibiotic-impregnated cement is also encouraged for a two-stage reimplantation, because it has been associated with the best overall results.

RESECTION ARTHROPLASTY

Resection arthroplasty is a treatment option for some patients who have a periprosthetic hip infection. The decision to perform a permanent resection arthroplasty without reimplantation of a second prosthesis is based on multiple factors, including:

- Infection with multiple organisms or bacteria resistant to antibiotic therapy
- Poor quality local soft tissues
- Unacceptable complexity of the reconstruction
- Refusal by the patient to have another operation after removal of the implant
- Patients with systemic disease and poor overall health
- Inadequate bone stock
- Combinations of these factors

Patients who have a resection arthroplasty can expect to have less pain than they did when the infection was present, but their functional recovery will be significantly impaired. These patients need aids to walk, have a noticeable limp, and must use a shoe lift to equalize the leg-length discrepancy and improve gait (1, 6, 23-34, 45).

INFECTED TOTAL KNEE ARTHROPLASTY

PATHOGENESIS AND PATHOPHYSIOLOGY

From the inception of prosthetic joint replacement, total knee arthroplasty has been associated with a greater risk of infection than total hip arthroplasty. Although the rate of infection following total hip arthroplasty is less than 1%, the rate of infection following total knee arthroplasty is approximately 2%. The reason for this discrepancy remains unclear but may be related to the fact that the implants are more superficial in the knee, and the limited amount of well-vascularized muscle and tissue surrounding the knee impairs local defense mechanisms.

As was previously discussed, a variety of pathogenic may be responsible for an infected total knee arthroplasty. The most common organisms, however, are S. aureus (50% to 65%) and S. epidermidis (25% to 30%). Other bacteria, fungi, and mycobacterium accounted for only 10% to 15% of the infections (63,69).

Other risk factors for infection are rheumatoid disease, open skin lesions, a previous history of surgery about the knee, and a previous history of infection (48,59-60). The risks associated with open skin lesions and other systemic infections are modifiable. Any medical condition that impairs the well-being of the patient, such as diabetes mellitus, poor nutrition, advanced age, or obesity, may increase the potential for infection.

Careful preoperative evaluation and treatment before an elective total knee arthroplasty can minimize the risk for postoperative complications. The greatest risk for infection is associated with a previous infection of the knee. Wilson et al. (69) reported a rate of infection of 3.1% in a study of 1,857 osteoarthritic knees that had had a revision total knee arthroplasty because of an infection around the previous implant (69). Rheumatoid disease, in addition to being associated with the risk of acute infection, is also associated with a risk of late infection secondary to hematogenous bacterial seeding of the knee. The risk of late infection in these patients is high; Wilson et al. (69) reported that late infections accounted for 45 of the 67 infections in a series of 4,171 total knee arthroplasties.

DIAGNOSIS

A patient who has an infection at the site of a total knee arthroplasty usually presents with a painful, warm, swollen, and stiff joint. The differential diagnosis of pain at the site of a knee replacement includes mechanical loosening of the components, reflex sympathetic dystrophy, heterotopic ossification, and arthrofibrosis. Evaluate patients in whom infection is suspected with pertinent physical exam, plain film radiographs, and laboratory evaluations, as discussed earlier. The key to diagnosis of infection in a total knee replacement is usually aspiration of the joint and analysis of the fluid with a Gram stain, complete and differential cell counts, and cultures. In a study of a consecutive series of 69 knees in 67 patients, Barrack et al. (4) reported that the results of aspiration had a sensitivity of 75%, specificity of 96%, and accuracy of 90%. These results support the routine use of preoperative aspiration before revision of a total knee prosthesis.

The major problem encountered in this study was the relatively common occurrence of antibiotic use among patients with symptomatic total knee replacements, which can increase the risk of false-negative results. Patients should be carefully questioned about their use of antibiotics. Delay or repeat aspiration 2 weeks after discontinuation of antibiotics. Aspirate the joint under meticulously sterile conditions to minimize the risk of contamination with skin flora. Local anesthetics are not recommended because of their bacteriostatic properties.

Sometimes it is not possible to identify an organism definitively in spite of a suspicious or convincing clinical course characterized by pain and loosening of the components. In these cases, staged reconstruction is commonly performed, and it is only with direct culture of the tissue membrane beneath the implant or material obtained by swabbing of the component that an organism is identified.

TREATMENT

Once the diagnosis of infection has been established, determine the most appropriate treatment regimen. The issue is often a complex one, because the surgeon must weigh the anticipated quality and longevity of life and expected function against the extensive surgery and course of treatment required to eradicate the infection. Removal of the infected implants, treatment with appropriate antibiotic therapy, and eventual reimplantation of a prosthesis, is the ideal.

A variety of circumstances might require an alternative treatment plan, however. The patient may be quite elderly, have multiple medical problems that would increase surgical risk, have other conditions that cause functional impairment, or have a well-fixed prosthesis. In these types of patients, the morbidity associated with removal of the prosthesis may be greater than that associated with chronic antibiotic suppression with preservation of the knee joint.

Retention of the Prosthesis

Retention of the prosthesis is generally feasible only in the setting of an acute infection with an onset within 10 to 21 days of the operation, with a susceptible...
gram-positive bacteria and no evidence of mechanical loosening. If antibiotic therapy alone is initiated within 48 hours of onset, a success rate of 6% to 10% has been reported in several large studies. Rates of success may be improved to approximately 23% by performing open debridement and synovectomy (53). This approach, however, requires long-term antibiotic suppression in an effort to contain the infection indefinitely. Rates of success are generally even lower in patients who develop infection more than 21 days after initial implantation.

Removal of the Prosthesis
Resistance of implant infections to treatment has been attributed to the environment of the implant surface and adherent bacteria that produce a biofilm (27). This biofilm provides an environment for the bacteria that is resistant to antibiotics and host defenses. Surfaces covered with biofilm may be surgically inaccessible to even the most aggressive debridement. Therefore, it is widely accepted that removal of the prosthesis is imperative when eradication of the infection is a primary goal. Surgical options include resection arthroplasty, arthrodesis, reimplantation in either one or two stages, and amputation.

Although resection arthroplasty is rarely selected as the definitive treatment, it remains a reasonable option for patients such as those who have rheumatoid arthritis and may have involvement of multiple joints. It is also reasonable for those with limited functional goals and a prospect for walking only with the assistance of a walker or other ambulatory device. Arthrodesis precludes a reoperation about the knee. In such patients, modest motion is preserved, usually in the range of 45°, it allows function for activities of daily living, although a brace is usually needed for ambulation. In a study by Falahieh et al., overall patient satisfaction approached 80% and most patients had good or excellent relief of pain (17).

Arthrodesis
Arthrodesis of the knee is an option that can provide a more stable lower extremity at the expense of motion at the knee. After an arthrodesis, the ability to walk independently depends on good function of neighboring joints of the lower extremity. Relative contraindications to arthrodesis include ipsilateral ankle or hip disease, severe segmental bone loss, contralateral leg amputation, and bilateral knee disease.

- Expose the prosthesis through the previous surgical approach.
- Remove the prosthesis, and thoroughly excise all scarred and infected tissues; carefully contour the bone ends. Consider placing cancellous bone grafts about the periphery of the arthrodesis.
- Place the knee in slight flexion of no more than 20°.
- Apply a rigid biplanar external fixator to obtain a compression arthrodesis, which is combined with prolonged immobilization. Time to union can vary considerably and depends on multiple factors.

An alternative is intramedullary nailing performed in a staged fashion, with removal of the prosthesis and debridement of the infected area, followed by antibiotic therapy and placement of the intramedullary nail at a later date. This alternative carries risks similar to those of reimplantation, namely multiple surgeries and the risk of contamination and spread of infection. The problems inherent with arthrodesis are bone loss, shortening, and gait disturbance. Knee arthrodesis also results in an increased energy expenditure for ambulation (47).

Single-stage Exchange
As noted above, removal of the infected prosthesis along with antibiotic therapy is the ideal initial treatment for infected total knee arthroplasty. Reimplantation of a new total knee prosthesis is the most acceptable option after removal of the infected prosthesis for providing the patient with a functional joint. Historically, reimplantation was done in a single operation, with success rates ranging from 50% to 75% (46, 60). More recently, two-stage or delayed reimplantation has become the accepted procedure. The use of antibiotic cement, however, aggressive surgical debridement, and newer antibiotic regimens have led to the development of more protocols for immediate or early exchange of an infected knee replacement.

Goksan and Freeman (24) reported successful eradication of infection at 5 years in 17 of 18 patients treated by a single-stage protocol, which included aggressive debridement, the use of antibiotic-impregnated cement, and a 3-month course of antibiotics. The only recurrence was in a patient with severe rheumatoid disease with multiple joint involvement. All of the patients in this group were infected with gram-positive organisms and had no systemic signs of sepsis. Such studies suggest that one-stage reimplantation may be a reasonable alternative in carefully selected patients and has the advantage of avoiding the added morbidity of another operation (24).

Two-stage Reimplantation
Removal of the implant, radical debridement, and an interval period of intravenous antibiotics followed by reimplantation remains the standard treatment of the infected total knee arthroplasty in most cases. It is commonly accepted that this approach gives the patient the best chance of eradication of infection. As previously noted, all foreign material, including the implant and all bone cement, must be removed at the time of the initial debridement.

Clean the bone meticulously and insert an antibiotic-impregnated cement spacer between the femur and the tibia. The antibiotic spacer preserves the joint space for later reimplantation, permits stability with weight bearing across the resected knee joint, and provides local antibiotics. The disadvantages of the spacer are the potential for erosion of adjacent bone, and after the elution of antibiotics ceases, it may act as a foreign body.

Continue administration of the appropriate parenteral antibiotic for at least 6 weeks. Controversy still exists regarding the total duration of antibiotic treatment, with some advocating the administration of an additional 6 weeks of oral antibiotics (2). Discontinue antibiotics at least 6 weeks before reimplanting the prosthesis. Consider reimplantation if the culture is negative. Repeat arthroplasty is usually performed between 12 weeks and 1 year after resection. The technical aspects of delayed reimplantation are more complex than those of standard revision due to problems of exposure, bone loss, ligamentous balance, and restoration of flexion.

Although staged reimplantation is plagued with numerous potential problems and requires careful management, results can be quite rewarding. Goldman et al. (25) reported on a series of 64 infected total knee replacements in 60 patients who were followed for an average of 7.5 years. At follow-up, six knees (9%) had become reinfected, but only two with the same organism, yielding an infection eradication rate of 97%. Most patients were satisfied with their function and outcome following surgery. The authors concluded that two-stage reimplantation with a 6-week course of parenteral antibiotics is an effective means of eradicating deep infection and providing a functional knee. The long-term functional results, reinfection rate, and survivorship are comparable with those found in revision total knee arthroplasty without infection.

Amputation
The alternative of amputation is usually reserved as a final option in the treatment of life-threatening infection or in the setting of a particularly virulent or resistant organism. It is only infrequently required but can provide an expedient resolution to a very difficult problem. Unfortunately, a poor functional result is the rule, with only one third of patients retaining the ability to walk, even with assistive devices, and the remaining two thirds confined to a wheelchair (46). Above-knee amputation (AKA) is seldom necessary and prosthetic fitting of an AKA prosthesis is rarely successful in these elderly patients.

Antibiotic prophylaxis for patients with total joint replacement
The incidence of deep postoperative total joint arthroplasty infection has been dramatically reduced over the past 25 years with the use of prophylactic antibiotics, careful surgical technique, maximizing the patient's health before surgery, and controlling bacterial contamination of the wound. Of these factors, prophylactic antibiotic therapy used routinely for patients undergoing total joint replacement is the most important. Several studies have documented the efficacy of prophylactic antibiotic therapy compared with placebo in preventing deep postoperative infection in total joint arthroplasty patients.

Carlsson et al. (11) published the results of a double-blind investigation of the value of prophylactic antibiotic therapy in early and late infections after total hip replacement (11). The early (2-5-year) follow-up of 118 patients showed no infection in the 60 patients who received prophylactic antibiotics compared with seven infections in the 58 patients who did not receive prophylactic antibiotics. The 5-year follow-up of the same patients also showed a difference, with two infections in the 60 patients who received prophylactic antibiotics and 14 infections in the 58 patients who did not receive the antibiotics.

A second study by Hill et al. (31) also documented the reduction of infection in patients administered prophylactic antibiotics compared with patients administered a placebo. The criticism of their review was that other factors were not controlled, such as the type of operating room used. It is known that laminar air flow, body exhaust suits, careful patient selection, ultraviolet light, and limiting operating room traffic all contribute to a decrease in the infection rate.
Cephalosporins remain the antibiotic of choice to prevent infection after total joint arthroplasty. Administer the antibiotic intravenously one-half hour before the incision is made to achieve bactericidal levels at the time of the initial incision. If the operative procedure is prolonged or exceeds the half-life of the antibiotic selected for prophylaxis, administer an additional dose. Continuing prophylactic antibiotics beyond 24 hours after surgery has not been shown to increase efficacy. This practice increases cost and may contribute to the emergence of resistant organisms. One exception to the routine use of cephalosporins may be in hospitals with a high percentage of methicillin-resistant strains of staphylococcus. Otherwise, the prophylactic use of vancomycin and other second-line antibiotics is discouraged to reduce the emergence of resistant bacteria.

The role of prophylactic antibiotics in preventing late or hematogenous infections is less clear. If prophylactic antibiotics are not used and the artificial joint becomes infected, the complication is catastrophic. The risk of such an occurrence in healthy patients, by contrast, is very small. Factors that argue against the use of prophylactic antibiotics include the very high cost of administering antibiotics to hundreds of thousands of patients per year, the possibility of anaphylactic reaction from the antibiotics, and the resistant strains of bacteria that emerge because of the overuse of prophylactic antibiotics.

It is likely that bacteremias associated with acute infection in the oral cavity, skin, respiratory, gastrointestinal, and urogenital systems and other sites can and do cause late implant infections. Two important factors to be considered are the amount of expected bacteremia from mucosal injury and the integrity of the patient’s host defense mechanisms. In general, administer prophylactic antibiotics appropriate to the endogenous flora immediately before any procedure that has a significant risk of mucosal injury, such as peridental surgery, or in patients with host defense impairment such as collagen diseases.

After careful consideration and review of all available data by an expert panel of dentists, orthopaedic surgeons, and infectious disease specialists, the American Academy of Orthopaedic Surgeons issued an advisory statement regarding the need for prophylactic antibiotics in dental patients who have undergone total joint arthroplasties. They concluded that antibiotic prophylaxis is not indicated for dental patients with pins, plates, and screws, nor is it routinely indicated for most dental patients with total joint replacements. It is advisable, however, to consider premedication in a small number of patients who may be at potential increased risk of hematogenous total joint infection (Table 135.4). The Academy also modified antibiotic regimens to eliminate the need for second doses (Table 135.5).

A 27-year-old man sustained an open fracture of the shaft of the right femur secondary to a low-velocity gunshot wound. Postoperative AP radiograph. This wound was treated with irrigation and debridement, and immediate locked intramedullary nailing as well as parenteral antibiotics. Postoperative lateral radiograph. This fracture healed nicely, but 4 months later, the patient developed a localized abscess at the fracture site. This AP radiograph shows periosteal new bone at the fracture site. Lateral radiograph showing periosteal new bone at the fracture site. This was treated with incision and drainage of the abscess, removal of the intramedullary nail, cross-screws and reaming of the intramedullary canal to debride it, as well as administration of parenteral bacterial antibiotics. This AP radiograph taken 4 months later shows the healed fracture with resolution of the bone infection.
Early Infection After Internal Fixation

The method of treatment of infection after internal fixation is based upon:

- The time of onset after internal fixation.
- The status of fracture healing.
- The stability of the implants and fracture.
- The extent of radiographic bone involvement.
- The type and virulence of the organism.
- The patient's general condition and health (Fig. 135.2).

Figure 135.2. Algorithm for treatment of acute infection after internal fixation.

Infections that arise in a patient within the first 4 weeks after internal fixation are generally considered early infections. Pain, fever, and wound drainage are the typical signs and symptoms. Plain radiographs usually show no signs of loosening or chronic osteomyelitis.

Acute infection may occur in the immediate postoperative period (i.e., the first 1 to 4 weeks) and may be characterized by either persistent drainage and an otherwise unremarkable appearing wound or by acute cellulitis, sometimes with systemic signs of infection. The differential diagnosis is a large hematoma and sometimes thrombophlebitis. If other signs of thrombophlebitis are present, perform a Doppler ultrasound examination first. Otherwise, immediately return the patient to surgery. Open the surgical wound down to the bone and implants. Send any fluid found and selected specimens of the deep soft tissues and a small biopsy of bone for immediate Gram's stain, culture, and sensitivity tests. Thoroughly debride and irrigate the wound. Ensure that the implants are stable. If a bone graft was placed at the time of the initial surgery, and gross purulence is not found, leave it in place. If gross purulence is found, most likely it will need to be removed, because it is a significant nidus for infection.

As soon as specimens are obtained, begin intravenous antibiotics. The choice of antibiotics is based on the results of the Gram stain or on what are the most likely infecting organisms in your hospital and in the patient you are treating, taking into account his or her clinical condition.

In most cases the wound can be closed in a routine fashion, unless gross purulence and poor conditions of the soft tissue contraindicate closure.

Most trauma surgeons close over antibiotic-impregnated beads without the use of suction or suction irrigation. If beads are not used, place closed suction drainage. Depending on the virulence of the infection and the patient's clinical response, returning the patient to surgery for repeat irrigation and debridement may be necessary on one or more occasions until the acute local infection is resolved. If antibiotic beads are used, insert a new set of beads at the time of each repeat irrigation and debridement.

If the wound has a benign appearance, or just a hematoma or seroma is found and cultures are negative, systemic antibiotics can usually be stopped when the wound is healed, the CRP level has returned to normal, and there is no further evidence of infection. If cultures are positive, then intravenous antibiotics, perhaps followed by oral antibiotics, are recommended for periods ranging from 4 to 8 weeks. In some cases, oral suppressive medication may be necessary until the fracture is healed and implants are eventually removed (12,41).

The treatment of acute infections varies depending on the type of implant in place. If external fixation is present, then simply ensure that all of the fixation pins are tight in the bone and not directly involved in the fixation suffices. External fixation is the most ideal type of fixation in the presence of infection because it minimizes the surface areas available for glycocalyx-forming bacteria to adhere to. In the case of plates and screws, the procedure is performed as described earlier, as long as the implants are solid in bone.

In the case of intramedullary nails, a decision must be made as to whether the infection involves just the outside of the bone or whether it has invaded the intramedullary canal. This decision can be difficult to make. If there is no gross purulence and the intramedullary canal does not seem to be involved, then leaving the rod in place and following the patient clinically is usually advisable. It may be impossible to irrigate around a solid nail, but exchange nailing may be necessary to debride the canal adequately (12,63; see Fig. 135.3). If there is gross purulence, however, and the implant appears to be loose or the medullary canal involved, then removal of the nail and cross-screws and conversion to external fixation is usually prudent. Another alternative would be to maintain the patient in a cast or traction, hoping that if the infection shows an excellent response to treatment that early reimplantation of the rod may be possible. If the rod is removed, debride the canal by reaming somewhat larger than the nail used. Culture the medullary contents.

Figure 135.3. A 15-year-old girl with type 1 diabetes mellitus had a varus malunion of the right midshaft tibia due to a closed tibial fracture treated in a plaster cast. This AP radiograph shows excellent correction of fixation. C: Unfortunately, 3 weeks postoperatively, the patient developed an acute wound infection. Initially, this wound was irrigated and debrided, and the nail was left in place. Because of inability to control the infection, the nail and cross-screws were subsequently removed and the patient was converted to a single plane external fixator. These AP radiographs show excellent maintenance of correction and good bone apposition at the fracture site. Fortunately, this wound healed and her infection has resolved.

Late Infection After Internal Fixation
In patients with subacute or late infections, symptoms may be less obvious (Fig. 135.4). Often, the only symptoms are vague, deep pain with minimal signs of local inflammation. Others may present with classic signs of acute inflammation and abscess formation. Laboratory values may be consistent with acute inflammation with elevated ESR and CRP levels. Radiographic signs of infection are often present. Frequently there is evidence of hardware loosening, screw backout, and implant failure, sequestrum formation, resorption of bone ends, and permeative cortical lysis. Again, an assessment of fracture healing is paramount and can be aided by tomography.

Figure 135.4. Algorithm for treatment of late infection after internal fixation.

In fractures with delayed union or nonunion that are infected, surgical treatment is nearly always necessary and begins with debridement of bone and soft-tissue abscesses, removing all infected and nonviable tissues. In the presence of delayed union or nonunion, implants are almost always loose. Convert unstable fixation to stable external fixation, and administer culture-directed parenteral antibiotics (12,41,63). Remove infected intramedullary implants, and debride the medullary canal by reaming.

The sequence of serial wound debridements, leaving the wound open, or managing it with close suction irrigation or antibiotic impregnated beads is performed as described for acute infection earlier. Administration for at least 6 weeks of parenteral antibiotics to which the organism is sensitive is nearly always necessary.

After local control of the infection is achieved, repeat internal fixation may be possible but the vast majority of cases are managed with external fixation. In the case of intramedullary nails, it may be possible to reinset a statically locked new larger nail if the infection is of low virulence and the organisms are sensitive, but a majority of cases will require definitive management in stable external fixation.

Now direct your attention to achieving bone union. In most cases, application of autologous cancellous bone graft is best. When segmental bone deficiency is present, a microvascularized bone transfer or bone transport using Ilizarov's technique may be necessary. Electrical stimulation has little role in these cases but can be used as a supplemental treatment.

Traditionally, bone grafting has been delayed until the wound is drainage free for 3 to 6 months, except in the Papineau technique, in which grafting can be carried out as soon as the bone is covered by a clean granulating bed (63). Patzakis et al. (64) challenged the delayed bone grafting concept by treating 32 patients with septic nonunions of the tibia with a protocol of irrigation, debridement, external fixation, and bone grafting at an average of 8 weeks after wound coverage. With this protocol, they achieved infection control in all of their patients and union in all but three patients. Union was achieved in these three patients after additional bone grafting.

The decision to persist with reconstruction of a septic nonunion must be weighed against the economic and human cost of such a complicated operative course. Lerner and others have shown the impact of such a treatment course on the patient's quality of life (5,23,30).

LATE INFECTION WITH A HEALED FRACTURE

In some patients, infection persists despite bone union. Generally, infections are the result of hematogenous seeding or result from a prior infection harbored in a retained sequestrum or the secretion of the glycocalyx on the fixation device. In the absence of a prior infection, it can be assumed that the hematogenous seeding is the cause of the infection.

To treat, drain any abscess, debri de necrotic bone and soft tissue, and remove all fixation devices. In the case of intramedullary fixation, ream the canal to complete the debridement. Significant bone involvement requires prolonged antibiotic therapy. Patients with minimal bone involvement and simple hardware removal can generally be treated with a short course of antibiotics until their wounds are healed and their CRP levels have returned to normal. The vast majority of these infections resolve after hardware removal.

ORTHOPAEDIC MANAGEMENT OF HEMOPHILIC ARTHROPATHY

James V. Luck Jr., Judith C. Lin, Carol K. Kasper and Laurence J. Logan

Hemophilia is inherited as a sex-linked recessive trait, with an incidence in the United States of 1 in 10,000 male births. Factor VIII deficiency, or hemophilia A, represents about 85% of these cases, and factor IX deficiency, or hemophilia B, accounts for 15%. Cases with a negative family history are considered de novo occurrences and are the result of a recent genetic mutation that accounts for 25% of new hemophilia A cases. This mutation rate is one of the highest among genetic disorders.

The original article on hemophiliar arthropathy is credited to König (35), who described the gross articular changes in 1892. Detailed descriptions of the microscopic pathology followed in 1925 by Freund (19) and in 1929 by Reineke and Wohlwill (63). The first papers in English were radiologic descriptions in 1921 by Klason (27) and in 1926 by Doub and Davidon (15). In 1932, J. Albert Key (34) presented the gross and microscopic findings in hemophilic arthropathy. His paper included a fascinating description of a 13-year-old boy who presented with a "tumor" about the knee. This patient had a negative family history for bleeders, but he had a history of easy bruising, nosebleeds, and periodic joint swelling. It was only after a synovectomy and stormy postoperative course that he was discovered to be a de novo hemophiliac. In 1936, Henry Thomas (70) described orthopedic findings in 98 hemophiliacs. Over the last six decades, the volume of scientific literature on hemophilic arthropathy has greatly expanded with many excellent papers and several complete texts (6, 13, 14, 17, 26, 66, 72).

PATHOPHYSIOLOGY

The course of hemophilic arthropathy is all too often unrelenting, progressing from hemarthrosis to chronic synovitis to extensive joint surface erosion and, ultimately, to end-stage joint destruction (Fig. 136.1, Fig. 136.2, Fig. 136.3, Fig. 136.4, Fig. 136.5, Fig. 136.6 and Fig. 136.7; see also Color Fig. 136.2). End-stage arthropathy is complicated by severe loss of motion secondary to arthrofibrosis as the hypertrophic synovium is replaced by dense fibrous scar. Severe contractures, angular deformity, and loss of bone stock due to synovial cysts and mechanical abrasion are common. The pathophysiology has been intensely studied, but our understanding remains incomplete. Chronic synovitis and progressive arthropathy have been reproduced in rabbits and dogs by serial intra-articular injections of autologous blood (20, 63). Gross and microscopic examination of hemophilic arthropathy reveals destruction of articular cartilage by direct synovial invasion and subchondral synovial and degenerative cysts. Biochemical studies have documented enzymatic degradation similar to other forms of inflammatory arthritis (6, 66). Symmetry is common, and in that sense, the condition is similar to rheumatoid arthritis.

Figure 136.1. AP (A) and lateral (B) x-ray study of a 14-year-old boy with severe hemophilia type A. The cartilage interval is well maintained. There are minor surface irregularities and an erosion on the posterior surface of the lateral femoral condyle.

Figure 136.2. A: Photograph of the knee of the patient in Figure 136.1 at the time of open synovectomy a few days after the x-ray studies were taken. There is extensive hyperplastic synovitis with full-thickness erosion of the articular surface of the weight-bearing surfaces of the medial and lateral condyles and the trochlea. This demonstrates the advanced destruction that can occur with chronic hemophilic synovitis despite a relatively benign-appearing x-ray study. B: Photomicrograph of the synovium from this patient showing hemosiderin pigment deposition on the surface taken up by the phagocytic synovial A cells. These cells migrate into the perivascular tissue of the subsynovial layer to return blood products to the general circulation. This patient was in the stage of chronic hemarthrosis, which is easy to understand with dilated venous channels immediately beneath the surface that are easily torn when the fragile, hypertrophic synovium gets caught between the eroded joint surfaces. (See also Color Fig. 136.2)
The joints most commonly involved are knees, elbows, and ankles. Hips, shoulders, and subtalar joints are sometimes involved; wrists, fingers, and toes are rarely involved. Fortunately, hemophilic arthropathy of the spine does not occur. The prevalence of hemophilia arthropathy correlates with the level of circulating clotting factor. Polyarthropathy is common in severe hemophilia (defined as less than 1% of normal circulating clotting factor), Arthropathy is much less common in moderate hemophilia (1% to 4% of normal clotting factor) and rare in mild hemophilia (greater than 5% of normal clotting factor).

Susceptibility to target joint formation varies from joint to joint within the same patient. The first hemorrhage may initiate a smoldering, low-grade synovitis with recurrent, subclinical bleeding, which results in a steady progression to chronic synovitis and end-stage arthropathy. However, a major joint may remain normal through adulthood despite the occurrence of a few hemorrhages in childhood and adolescence. The biochemical and pathophysiologic reaction of the synovium to hemarthrosis varies even within the same patient and probably involves an element of autoimmune sensitivity.

NONOPERATIVE MANAGEMENT OF HEMOPHILIC SYNOVITIS

PROPHYLACTIC CONCENTRATE

Aggressive use of clotting factor concentrate in the early phases of hemophilic synovitis may reverse the progressive nature of this disease in some cases, but even with optimal management, many patients will progress. Chronic synovitis reaches a point at which the membrane becomes very friable, with dilated venous channels immediately beneath the surface. This is the stage of chronic hemarthrosis and is usually associated with joint surface erosions. With motion of this jagged joint, the friable, hyperemic synovium is torn, resulting in bleeding regardless of clotting factor level (Fig. 136.1, Fig. 136.2). Muscles atrophy, joint contractures develop, and the patient becomes severely disabled (Fig. 136.3, Fig. 136.4).

Because of the often inexorable course of hemophilic synovitis, management of initial hemorrhoses is critical if a normal joint is to be preserved.

- Start clotting factor concentrate as soon as possible after the onset of bleeding.
- If the hemorrhage is clinically significant, consider aspiration to reduce the magnitude of blood breakdown products to which the synovium is exposed as well as to reduce pain and facilitate recovery.
arterial bleeding. Articular cartilage is highly radioresistant, and although damage is theoretically possible, none has been reported. Progressive degeneration of treated joints over the last 20 years, many centers have treated pediatric patients with radiosynovectomy. Therefore, intra-articular injection should not reach the growth plate. To date, there have been no reported cases of growth plate disturbance (excellent) or greater than 75% reduction in frequency of hemarthroses (good) (Table 136.1). Results from several centers have been remarkably consistent, with about a 75% rate of good and excellent results defined as complete cessation of hemarthroses formation subject to recurrent hemarthroses without trauma may occur.

The initial bleed usually occurs during early childhood, most commonly in the ankle, followed by the elbow and knee. In recent years, several hemophilia centers have begun programs of primary prophylaxis before the first bleed. Regular doses of clotting factor are begun at 1 to 3 years of age and continued into middle to late adolescence. This approach is based on the experience with moderate hemophilias with factor levels of 1% to 4% of normal who grow up with a paucity of joint hemorrhages and are often free of arthropathy when they reach adulthood (53). This approach is very costly and usually requires a venous access port with a significant risk of infection. Fortunately, recombinant factor is now available and free from viral contaminants.

On the horizon is gene therapy, which promises to be the ultimate answer for prevention of arthropathy. In the meantime, older children, adolescents, and adults continue to be plagued by chronic synovitis and progressive arthropathy. Early synovectomy holds some promise for the prevention of progressive arthropathy in target joints.

About 15% of factor VIII–deficient and fewer factor IX–deficient patients develop antibodies termed inhibitors to human clotting factor (4). Treatment with immune tolerance programs, in which patients are given large amounts of clotting factor to overwhelm and suppress the inhibitor, are often successful for these patients. Although these programs are costly, in the range of $200,000 to $800,000 per patient, immune tolerance is greatly beneficial to the patient and may be ultimately cost effective because it prevents hemorrhage and progressive arthropathy. Patients with persisting inhibitors are like hemophiliacs before the days of any effective treatment. They are extremely complex to manage, and major trauma or surgery creates a precarious situation; they are not candidates for surgery other than in life-threatening emergencies.

ARTHROSCOPIC SYNOVECTOMY

Synovectomy is the treatment of choice for hemophilic synovitis, ideally before irreversible joint destruction has occurred. Synovectomy may be surgical, either open or arthroscopic, or through the injection of radioactive colloid. Open synovectomies were first performed in the late 1960s, when clotting factor concentrate (67) became available. Although these procedures were effective in reducing or eliminating hemarthroses, they were complicated by severe arthrofibrosis and loss of motion, and there was one report of arteriovenous fistula (1,12).24,48,60,72. Because of the complexity and prohibitive cost of the administration of concentrate for this procedure, most patients now undergo joint surface excision by the time synovectomy was eventually performed, and joint surface degeneration progressed over the ensuing years. In that era before arthroscopy and magnetic resonance imaging (MRI), findings at surgery showed a surprising degree of surface erosion that was unsuspected based on the plain radiographs (Fig. 136.1 and Fig. 136.2). With the advent of arthroscopic surgery, arthroscopic synovectomy replaced open procedures and was associated with much less loss in motion but was occasionally complicated by significant hemorrhage in the perioperative period (15,43,76). Massive amounts of factor replacement were still required for 2 weeks following surgery and before physical therapy for as long as the therapy was needed, so the prohibitive cost of administering concentrate remained about the same.

RADIOSYNOVECTOMY

Radiosynovectomy, or radiosynoviorthesis, which is a term preferred by some, was introduced in 1963 and has been used extensively for rheumatoid arthritis (5). Over the last 20 years, several hemophilia centers outside the United States have used a variety of radiocolloids for chronic hemophilic synovitis (2,3,18,63). In 1988, with institutional review board approval, the Hemophilia Center at Orthopaedic Hospital in Los Angeles (OHHC), began a prospective study of radiocolloid synoviorthesis in the treatment of chronic hemophilic synovitis.

32P Chronic phosphate is the agent of choice for radiosynovectomy in the United States and Canada. The dosage protocol is also quite universal (Table 136.1). To date, the procedure has not been performed on hips at OHHC.

All patients receive a dose of clotting factor just before the procedure that is aimed at attaining a plasma level of clotting factor of 50% of normal and are advised to self-infuse a second time 8 to 12 hours following the procedure. Patients with inhibitors receive the clotting factor that has been the most effective in controlling their bleeding episodes. They are observed overnight in the hospital. The procedure is as follows:

1. Prepare the involved joint with povidone-iodine and drape it with sterile towels.
2. Infiltrate lidocaine 1% into the skin, subcutaneous tissue, and capsule with a 27-gauge needle. Buffered lidocaine is less painful and is especially useful in children. Lidocaine-prilocaine lotion applied to the skin 1 hour before injection also reduces pain.
3. Insert a larger needle ranging in gauge from 23 to 18, depending on the amount of fluid to be aspirated, into the joint space. Needles larger than 22 gauge are not used in subcutaneous joints such as the elbow to avoid retrograde leakage of radiocolloid onto the skin. The intra-articular position of the needle is critical; complete lack of column fluid occurs if the needle is not in the joint space. Needles with image-intensifier visualization assist with needle placement.
4. After confirmation of needle position, inject the selected dose of radiocolloid in a volume of 1 ml through a separate syringe.
5. The needle is removed and partially inject a mixture of 5 ml lidocaine and 2 ml dexamethasone acetate into the joint. Use the remainder to flush the needle and needle tract as the needle is withdrawn to reduce the risk of radiocolloid leakage along the needle tract.
6. Apply local pressure. Followed by cleansing of the area with isopropyl alcohol, followed by more local pressure for a total of 3 to 5 minutes. While maintaining local pressure on the injection site, put the joint through range of motion to disperse the radiocolloid throughout the joint.
7. When the puncture site is completely dry, apply a small adhesive bandage.
8. Immobilize the treated joint for 2 days and have the patient avoid strenuous activities for 2 weeks.
9. Perform biodistribution analysis using a small window Geiger counter. Count the counts per minute for the target joint, contralateral joint, regional nodes, and liver. In addition, perform a single photon emission computed tomography (SPECT) scan to determine the distribution of the radiocolloid within the joint. Check the biodistribution at the time of the procedure, and after 1 day, 1 week, and 1, 2, and 3 months. Because of the large particle size, escape of the radiocolloid from the joint is much less frequent than with gold or yttrium. At our center, in 120 consecutive cases, only three patients demonstrated minute escape of the radioactive collod, ranging from 0.5% to 2.5% of the total dose in the target joint (46).

Results from several centers have been remarkably consistent, with about a 75% rate of good and excellent results defined as complete cessation of hemorrhoses (excellent) or greater than 75% reduction in frequency of hemorrhoses (good) (1,46,47,64). This success rate remains stable at 10 years follow-up.

Safety is a function of the local and remote effects of the radiation, with particular concern for damage to local tissues, such as the growth plate or articular cartilage, and the late development of a secondary neoplasm. Because 32P chronic phosphate is a pure beta emitter, this is not a concern.

Intra-articular injection should not reach the growth plate. To date, there have been no reported cases of growth plate disturbance (3,18). Furthermore, over the last 20 years, many centers have treated pediatric patients with 111In radiocolloid, which has both beta and gamma radiation, without apparent growth plate disturbance. Articular cartilage is highly radioresistant, and although damage is theoretically possible, none has been reported. Progressive degeneration of treated joints continues to be plagued by chronic synovitis and progressive arthropathy.
joints does occur, but the rate is equal to or slower than expected for the disease process (38,35,55,77).

The principal concern in radiosynovectomy is the potential of late radiation-induced neoplasia. External beam radiation has been extensively studied and carries a small risk of induction of bone sarcomas, principally osteosarcoma or fibrosarcoma. The peak incidence is 5 to 10 years after the procedure, but cases have been reported as early as 3 years (23,49). Because of the low penetration of 109P chronic phosphate, bone exposure is minimal. Furthermore, intra-articular sarcomas of any type are extremely rare. For example, synovial sarcomas and chondrosarcomas are almost never intra-articular.

Probably the strongest argument for the safety of intra-articular radioisotopes, is the long-term follow-up of the more than 5,000 radiosynovectomies performed for rheumatoid arthritis, none of which have been reported to develop radiation-induced malignancies (41). Five to 10 milli Ci of 109P were used on most of these patients since 1963. The small (20 mm) particle size of Au resulted in a 20% to 37% incidence of escape, usually to regional nodes (22,71,73). Yet, there have been no reports linking the use of this agent to hematogenous malignancies or sarcomas. In our series, the maximum escape was 2.5% of the targeted dose, which occurred in one patient (46). Winston et al. (73), using chronic phosphate in rheumatoid patients, reported a maximum escape in only one patient of 3.2%, which agrees closely with our results. Rivard (64), however, reported three patients with 7%, 9%, and 14% escape using chronic phosphate. Immunoblizing the treated joint for 2 days and limiting activities for 2 weeks may reduce the risk of escape. The small amount of intra-articular steroids used in our series may account for the absence of postinjection inflammation and bleeding reported in other series. This approach may further reduce the risk of escape.

SURGERY FOR HEMOPHILIC ARTHROPATHY

Before the release of factor VIII concentrate in 1966, major surgery for chronic synovitis or advanced hemophilic arthropathy was a rare undertaking fraught with an unacceptable rate of complications as a consequence of uncontrolled hemorrhage and systemic fluid overload from the transfusion of whole blood and fresh frozen plasma (31). Even with the availability of cryoprecipitate, surgery was mostly limited to the mild hemophilics with higher levels of circulating factor VIII or IX (13,14,57).

With the availability of factor VIII concentrate in the United States in 1967, major hemophilia centers began performing elective surgery on their patients (14,16,17,30,57). During the past 30 years, an interdisciplinary team of physicians at OHHC has performed more than 700 major surgical procedures on hemophilics. Our surgical philosophy and recommendations are based on that experience and a substantial volume of published reports and presentations from hemophilia centers around the world.

Factor VIII deficiency, or hemophilia type A, accounts for about 85% of hemophilia. Almost all of our joint replacement patients fall into this group. For many years, we were reluctant to consider major surgery on patients with factor IX deficiency, or type B hemophilia, because of the increased risk of life-threatening thromboembolic complications related to activated clotting factors in factor IX concentrate previously reported by our center (30). When purified factor IX became available in 1990, however, these patients also became elective surgical candidates (31). Rarely, patients with Von Willebrand’s syndrome and other clotting factor deficiencies will develop hemophilic arthropathy that requires joint replacement. Some will need joint replacement at an advanced age on the basis of osteoarthritis unrelated to their clotting disorder.

Kasper et al. (30) reported on a retrospective study of the first 15 years’ experience with clotting factor concentrate in elective surgery. The amount of concentrate used tripled during the study period, but the incidence of postoperative bleeding was not significantly reduced by the additional factor VIII replacement. The frequency of postoperative bleeding correlated better with the site and type of surgery than with the factor levels at the time of the incident. For example, the incidence of postoperative, surgical site hemorhagia was 40% for knee surgeries and 15% for all other types. These findings were similar to those reported by Kay et al. (32).

CURRENT REGIMEN OF CLOTTING FACTOR REPLACEMENT

- Preoperatively, carefully screen the patients for any evidence of a factor VIII inhibitor and any medical contraindications to elective reconstructive surgery.
- Elevate factor VIII levels to above 100% of normal 1 hour before surgery.
- Maintain factor levels at 80% by continuous infusion until the patient is discharged. This is cost effective because continuous infusion maintains a more consistent level than bolus therapy (25).
- If further, vigorous physical therapy is required to increase range of motion, infuse the patient to a 50% level before each therapy session.

With the increased emphasis on cost containment, we allow selected patients to leave the hospital after the first week and continue intermittent self-infusion at home. This is possible only for lesser procedures, such as radial head excision and elbow synovectomy, and in patients who are on the self-infusion program, live close to the hospital, and are eminently reliable.

Orthopaedic surgical intervention for hemophilic arthropathy may be divided into two categories based on the degree of arthropathy: synovectomy with or without debridement for early to moderate arthropathy, and reconstructive surgery for advanced arthropathy.

SURGICAL SYNOVECTOMY

The indications for surgical synovectomy vary among hemophilia centers depending on their interest in radiosynovectomy. Because radiosynovectomy is about 5% to 10% of the cost of surgical synovectomy and much easier for the patient, most centers favor that procedure for earlier cases. Surgical synovectomy is clearly indicated for cases who have very thick synovium (more than 5 mm) that prevents passage of beta-emitting radiocolloids, patients with significant arthrofibrosis requiring debridement, and patients in whom radiosynovectomy has failed. Arthroscopic synovectomy has almost completely replaced open synovectomy, except for patients who have very thick synovium (more than 5 mm) that would be beyond the penetration of beta-emitting radiocolloids, patients with significant arthrofibrosis requiring debridement, and patients in whom radiosynovectomy has failed. Arthroscopic synovectomy has almost completely replaced open synovectomy, except for patients with severe arthrofibrosis and loss of motion.

The indication for synovectomy is recurrent or chronic hemorrhagia that is unresponsive to appropriate conservative management in a joint with minimal arthropathy. A trial of conservative treatment usually requires 3 to 6 months. However, by the time these patients come to surgery, there is often a significant amount of full-thickness articular cartilage erosion and the remaining articular surface has sustained significant mechanical and biochemical insult (Fig. 136.1, Fig. 136.2A). Under these circumstances, synovectomy is rarely curative but is often effective in resolving the chronic and recurrent hemorrhages, and possibly slowing the progression of arthropathy (52,54). Resolution of the chronic hemorrhagia allows the patient to resume therapeutic exercises, often with marked improvement in function as well as reduction in hemarthroses and the need for coagulation factor replacement.

There is increasing interest in considering synovectomy before irreversible damage to the articular cartilage occurs. Surface erosion occurs early in this process, even before the synovial is noticeably symptomatic or clinically evident. Patients at this stage are often 3 to 8 years of age. If the safety of radiosynovectomy can be established for this age group, early intervention may become the standard. Early arthroscopic synovectomy is also an option because children are much more difficult to rehabilitate than adults after surgical synovectomy. The pediatric patient is not usually capable of exercising the knee if it is painful and often loses range of motion after this period is lost and occasionally after arthroscopic synovectomy if hemorrhage occurs. Small vessel hemostasis at the time of arthroscopic synovectomy is not possible with motorized shavers but would be possible with a laser. However, to date there is no large reported experience with laser synovectomy in hemophilia. For patients whose range of motion fails to progress postoperatively, consider closed manipulation 10 to 14 days postoperatively, followed by continuous passive motion (CPM) and 1 week of nonsteroidal anti-inflammatory drug (NSAID) therapy. This regimen is as effective as open debridement and has a lower rate of complications. For patients with very thick synovium (more than 5 mm) that prevents passage of beta-emitting radiocolloids, patients with significant arthrofibrosis requiring debridement, and in patients in whom radiosynovectomy has failed, arthroscopic synovectomy may be a viable alternative.

SPECIFIC JOINT CONSIDERATIONS

Surgical experience and current recommendations from our center are presented in the order of the frequency of joint involvement: knee, elbow, ankle and subtalar.

Knee

Arthropathy of the knee is the most common cause of pain and disability severe enough to require reconstructive surgery in hemophilics. Involvement of the ankle and elbow is about as common as that of the knee, but the ankle and elbow require surgical intervention less frequently. Historically, the range of procedures considered for hemophilic arthropathy of the knee included synovectomy, debridement, debridement with patellectomy, osteotomy, fusion, and total knee prosthetic arthroplasty.

Today at OHHC, we perform only arthroscopic synovectomy, open debridement, total knee prosthetic arthroplasty, and fusion. Previously, we performed distal femoral extension osteotomy for severe flexion contractions that failed to respond to physiotherapy or serial casting. Today, such deformities are much less common except in patients with advanced arthropathy and are corrected at the time of prosthetic arthroplasty. Preservation of the patella is especially important in this patient population who are prone to flexion contractures, especially following knee replacement. Patellectomy is occasionally indicated at the time of knee replacement when, either from erosion or prior surgery, there is inadequate bone stock for secure fixation of a prosthetic component.

Because of the complexity of postoperative rehabilitation and the risk of recurrent arthrofibrosis, patient motivation and careful preoperative counseling are very important. At OHHC, all patients are seen preoperatively by the surgeon, hematologist, physical therapist, and patient-care coordinator as a team for assessment and
We use arthroscopic or open debridement to treat chronic synovitis and early to moderate arthropathy. The principal indications for debridement are recurrent hemarthrosis that is unresponsive to conservative management and impingement symptoms, usually associated with recent loss of extension. In some patients, inflammation is a more prominent feature in others, in which case it may result from vigorous exercise or pain. Although debridement is widely used, it is not clear in this group of patients is usually intermittent and responds to nonsteroidal anti-inflammatory agents and analgesics. If pain is the principal symptom in a patient with moderately advanced to advanced arthropathy, debridement is rarely of lasting benefit. In our experience, at 7 to 21 years of follow-up, 6 of 18 patients who had undergone debridement required total knee replacement, four of them within 1 year. These patients were older at the time of debridement (average age, 30.8 years) than those who obtained lasting benefit (average age, 16.5 years), and they had arthritic pain as their principal complaint (43).

Open debridement is often complicated by loss in range of motion. Arthrofibrosis with loss of motion is one of the most significant complications of surgery for advanced hemophilic arthropathy (6, 40, 42, 50, 52, 53, 73, 75). In our series, the average loss of range of motion in the nine patients undergoing arthroscopic debridement was only 9°, but they had a 50% incidence of postoperative hemarthrosis compared to none in the open debridement group. This difference is attributed to the inability to achieve complete curettage with arthroscopic debridement, and thus, arthrofibrosis. Although early improvement may be obtained, the arthrofibrosis often recurs with a poor end result. Occasionally, lasting improvement in range of motion has been obtained following the injection of a long-acting local anesthetic and a nonsoluble cortisone preparation at the time of knee manipulation 7 to 14 days after surgery.

Primary knee fusion may be indicated for patients with end stage arthropathy and fibrous ankylosis, severe deformity, or infection. Seven primary knee fusions have been performed at OHHC. Two of these patients had a history of infection, one from a hematogenous pyarthrosis with Pseudomonas aeruginosa and another with chronic Staphylococcus aureus osteomyelitis after an osteotomy. Five of the patients fused without problems and with good long-term results, including the one patient with Pseudomonas infection before surgery. One of the patients herniated from the denuded bone surfaces and swelled to such an extent that the external fixator crossing the knee had to be removed. He healed without infection but has a pseudarthrosis that is stable and painless. He is fully ambulatory with a cylinder orthosis. The knee fusions fused in the third week in all but one patient with limited mobility and an intraarticular suction drain. The knee involvement can but can arise from an arthrosis without assistive devices. No patient has developed associated ipsilateral hip or low-back problems. We have performed no primary knee fusions in the last 15 years because we now favor total joint replacement. Patients with end-stage arthropathy and fibrous ankylosis usually have minimal or no pain and do not require surgery if the knee is near-full extension and adequately aligned.

The knee is the most frequently reconstructed joint for hemophilic arthropathy at OHHC. Knee replacement represents about 10% of all surgeries on hemophiliacs. The indications for knee replacement are the same in hemophilia as in other arthropathies: pain and disability that is unresponsive to conservative management with end-stage radiographic changes (Eti, 136-6). End-stage arthropathy may develop by late adolescence. Severe pain and disability often exist by the third or fourth decade. The age range at surgery in our series was 21 to 62 years, which is typical. Most patients are in their forth or fifth decade at the time of operation.

Chronic synovitis and extensive arthrofibrosis requiring careful dissection and definition of normal tissue planes complicate the surgical approach for knee replacement in these patients. It is important to preserve the fat layer in the supracondylar area of the femur, which is an effective barrier to adhesions between the extensor mechanism and the femur. Many patients have flexion contractures that require modified cuts on the distal femur as well as posterior capsular release. Our preferred method of posterior release is under direct vision through the usual anterior approach to the knee, as follows:

- Carefully dissect the posterior capsule off the distal femur with the knee in maximum flexion. Isotope your nondominant hand and use it to apply pressure to the posterior capsule just below its attachment to the distal femur to protect the popliteal structures from inadvertent laceration while dissecting the capsule off the femur with a small osteotome.
- Excision of popliteal synovitis as well as the posterior release are often facilitated by placing a self-retaining lamina spreader alternately in the medial and lateral compartments to separate the femur from the tibia and maintain tension on the capsule. Extensor mechanism contracture is also common. Quadricepsplasty may be required or be often results in loss of full active extension, which gradually recovers over the ensuing few months.
- Take care to maintain full passive extension postoperatively. Partial release, rather than complete transaction of the extensor mechanism, is preferable when it is adequate to allow 90° of flexion. A V-Y lengthening is performed for more severe cases. With diligent physical therapy, these patients often end up with 90° or more of motion.
- Close the wound in patients with limited preoperative flexion, with the knee in about 50° flexion.

The first knee replacements at OHHC were performed in 1974 and were of the two-compartment type. We began using three-compartment “total condylar” prostheses in 1978. Beginning in 1982, 18 bone ingrowth “cementless” prostheses were implanted. For the last decade, we have used cemented posterior stabilized knees exclusively. The age range at the time of surgery and pathology was very similar among these three groups. There has been a statistically significant difference between these groups in the survivorship of the prosthesis, which, without infection, is 96% projected to 20 years (43, 44). However, the eight knee replacements of the two-compartment type had an average loss of 10 degrees of range of motion, and three patients had residual patellofemoral pain. After converting to three-compartment replacements, range of motion improved an average of 30° for patients with a preoperative range of less than 80°. The probable reason for this gain in motion is inclusion of the patellofemoral joint replacement, but improved techniques, including the use of continuous passive motion postoperatively, also may have contributed. At present, we begin continuous passive motion the second postoperative day if the wound is doing well. We no longer use immediate postoperative continuous passive motion because it is associated with increased bleeding. Although the end results of the “cementless” knees were equivalent to our current cemented models, there was significantly increased blood loss postoperatively, as measured by Hemovac output.

Loss of bone stock is relatively common in hemophilic arthropathy owing to synovial cysts or mechanical erosion. Earlier solutions to this problem included filling defects with polymethylmethacrylate cement or the use of specially designed, stemmed components. During the last 18 years, bone grafting has been the procedure of choice. It is especially attractive because of the potential to improve bone stock if future revisions are needed in these relatively young patients. A minimum of bone is resected. Local autogenous bone is used for small and moderate-sized defects. Large defects require allograft. Autogenous iliac graft is not used because of the risk of hemorrhage and possible pseudotumor formation at the donor site.

Complications At OHHC, four types of significant early postoperative complications have occurred following knee replacement: hemarthrosis, Coombs-positive hemolysis, deep infection, and compartment syndrome. In one study, hematogenous infections were found in 1.4% of patients undergoing knee surgery on hemophiliacs was reported in 40% of patients regardless of the factor level (30). Perioperative hemarthrosis tends to occur in the patients who still have active, hypertrophic synovitis and are in the stage of chronic hemarthrosis. The intra-articular blood is partially clotted and impossible to aspirate. It should be evacuated using arthroscopic cannulas, followed by thorough lavage and the placement of a suction drain.

Coombs-positive hemolysis has been identified in only one knee replacement patient and was probably the result of minor host-donor incompatibilities present in earlier clotting factor concentrates. Clotting factor preparations are now purified, and there have been no instances of this hemolysis in the last 12 years.

Wound dehiscence occurred in one patient at the time of manipulation in the early days of knee replacement. Today, manipulation is rarely used. However, the capsule is always closed with nonabsorbable suture to reduce this risk, especially in the patient with arthrofibrosis who will undergo fairly vigorous physical therapy beginning a few days after surgery.

Aseptic failure of fixation from any cause occurred in three patients, each with single-component loosening: tibial component, femoral component, or patellar component. The femoral component failed when the patient fell and fractured his distal femur near the component. The failed tibial component, a Geomedic two-compartment replacement performed in 1974, was inserted in a patient with severe bone stock deficiency resulting from a large pseudotumorous cyst in the upper tibia, which was filled with cement. The failed patellar component was inserted into a patella that had eroded down to a thin cortical shell and did not have adequate bone stock for cement intrusion and fixation. The loose femoral and tibial components were treated by revision surgery, and the patellar component was treated by patellectomy. These three revision surgery patients have done well. The patellectomy patient regained active range of motion of 0° to 90°. The tibial component failure was revised to a Total Condylar III (Zimmer) prosthesis and did well for 9 years, until he died of hepatic carcinoma, a consequence of chronic hepatic failure. The patient with the femoral failure with the distal femur fracture was revised to a Total Condylar III (Zimmer) prosthesis and is doing well after 15 years. This represents an aseptic failure rate of 3 in 90, or 3.3%, at 2 to 24 years’ follow-up, which despite the young ages of these patients at the time of prosthetic arthroplasty, is comparable to a known failure rate with arthroplasties in rheumatoid arthritis and rheumatoid arthritis (27). The low aseptic failure rate for this relatively young population is probably due to their low activity level as a consequence of polyarthopathy. The principal mode of failure of prosthetic joints in hemophiliacs is late, hematogenous infection, which is discussed in a separate section of this chapter.

Elbow

Elbow synovitis and arthritis are common in hemophilia, but most patients are not symptomatic enough to warrant surgical intervention. Radionuclide synovectomy for persistent synovitis was effective in reducing hemarthroses in 78% of patients in our series (46). Under present protocols, at the time of radiosynovectomy, essentially all patients have some degree of joint surface changes. The synovectomy may forestall but will not prevent progression to advanced arthropathy. The only
open surgical procedure, in our experience, that is useful for patients with persistent synovitis and advanced arthropathy is radial head excision with synovectomy and debridement.

Indications for radial head excision with synovectomy and debridement include pain, chronic hemarthrosis unresponsive to nonoperative management, and loss of forearm rotation. The most disabling loss of motion in these patients is loss of supination on the dominant side. If it is less than 45°, it impairs the patient’s ability to eat normally, accept change, and accomplish personal hygiene. The major source of pain, recurrent bleeds, and restricted forearm rotation is derangement of the proximal radioulnar joint secondary to hypertrophy and marginal irregularity of the radial head. Hemophilic arthropathy of the elbow is often associated with marked hypertrophy of the radial head, which impinges against the proximal ulnar facet, inhibiting forearm rotation and trapping fragile synovium, resulting in hemarthrosis (Fig. 136.7). The patient’s pain is typically posterolateral. There is focal tenderness over the posterior aspect of the proximal radioulnar joint and increased pain with forearm rotation, especially supination.

![Figure 136.7](image1)

Figure 136.7. (A) and lateral (B) radiographs showing advanced hemophilic arthropathy of the elbow with massive enlargement of the radial head and synovial cysts on both sides of the joint resulting in deepening of the trochlear groove.

The level of resection of the radial head is just below the ulnar facet, which eliminates impingement but preserves part of the annular ligament for stability. Later proximal migration of the radius, causing distal radioulnar joint symptoms, has not been observed in our patients, all of whom were at least in their third decade at the time of surgery. This procedure is not recommended for immature patients.

Use a posterolateral surgical approach along the border of the anconeus (see Chapter 1). Following radial head excision, dissect part of the common extensor origin from the lateral epicondyle, to expose the ulnohumeral articulation. This dissection is aided by varus stress. Posterior exposure may be enhanced with further dissection of the capsule from the posterolateral humerus.

Pain relief with this procedure has been excellent in spite of advanced changes in the medial side of the ulnohumeral articulation, which is only debrided. Cessation of recurrent or chronic hemarthrosis occurs in approximately 90% of patients. In patients with restricted forearm supination preoperatively, radial head excision has resulted in an average gain of 30°, which has made a significant difference in the ability to perform activities of daily living. Occasional patients will have significant pain at the ulnohumeral joint, usually on the medial side, and some will manifest symptoms of a tardy ulnar palsy as a result of synovial invasion of the ulnar groove. These patients can be helped with ulnar nerve transposition and debridement of the ulnar side of the elbow.

Flexion-extension range is a function of the pathology in the ulnohumeral joint, its capsule, and the musculotendinous units crossing the joint. Loss of this range in chronic hemophilic arthropathy is a long-term process and is not altered significantly by radial head excision, even with ulnohumeral joint debridement. Increased range may be accomplished at surgery but is rarely maintained postoperatively.

Ankle and Subtalar Joint

The ankle is similar to the knee and elbow in frequency of involvement and is usually the first target joint in children after they begin to walk. Progressive arthropathy is the rule. End-stage ankle arthropathy is commonly manifested by severe joint surface erosion, valgus alignment, and opposing exostoses on the tibia and talus. Large synovial cysts occasionally invade the talus adjacent to the ankle joint (Fig. 136.6). The subtalar joint is also subject to hemophilic arthropathy, although involvement is less common than in the ankle (Fig. 136.9). Its involvement usually accompanies that of the ankle but can occur in isolation. Erosion of the posterior margin of the posterior facet, similar to that seen in rheumatoid arthritis, is the first manifestation of subtalar joint disease on plain radiographs. Many patients develop equinus deformities secondary to ankle arthropathy and calf bleeds with residual muscle contractures (Fig. 136.8, Fig. 136.10).

![Figure 136.8](image2)

Figure 136.8. Advanced arthropathy of the tibiotalar joint with surface irregularity, joint surface erosions, and abutting anterior exostoses.

![Figure 136.9](image3)

Figure 136.9. Isolated advanced arthropathy of the subtalar joint without tibiotalar involvement.
Only a small percentage of ankles require surgery. The procedure of choice for the ankle or subtalar joint is arthrodesis. Over the years, a variety of fixation techniques has been used, including Charnley external fixation, anterior plate and screws, and crossed screws. Crossed screws are our favored technique. For combined ankle and subtalar arthrodesis, we drill two or three cancellous screws from the tibia across the talus into the os calcis using a custom drill guide. The distal fibula often unites more slowly than the tibiotalar joint. A distal fibular ostectomy eliminates rotation stresses about the lateral malleolus. If the malleolus is unstable, the lateral malleolus may be compressed against the talus with a single transfixing screw into the tibia. In patients with moderate to severe equinus deformity and Achilles tendon contracture, a single-pin Charnley compression device may be placed through the anterior talus and tibia to maintain the foot in neutral and take stress off the internal fixation screws transfixing the ankle. Cast fixation alone may not be adequate in these patients without producing excessive pressure on the metatarsal heads.

The OHHC surgical experience includes 42 cases: tibiotalar arthrodesis, 34; tibiotalar and subtalar arthrodesis, 5; pantalar arthrodesis, 2; and tibiotalar prosthetic arthroplasty. 1. If the talonaviculai and calcaneocuboid joints are normal, they are not included in the fusion. Fixation techniques included 39 internal fixation and 3 Charnley external fixators. External fixators are safe in hemophiliacs and do not require clotting factor replacement after the initial 2 weeks. This is similar to the experience reported by Wilson et al. (78) and Patel et al. (59), but different from that suggested on theoretical grounds by Trueta (72) and Arnold and Hilgartner (6).

Postoperative Care Place all patients in a non-weight-bearing short leg cast for 6 weeks, followed by a weight-bearing well-molded short leg cast or a polypropylene ankle-foot orthosis (AFO) depending on the degree of consolidation evident on radiographs at 6 weeks. At 12 weeks, even if the fusion appears solid, continue an AFO until the fusion is solid and can withstand all daily activities.

Results Over the last 16 years, we have not seen progressive degeneration of the unfused midfoot joints following combined ankle and subtalar arthrodesis.

One patient with a tibiotalar joint treated with external fixation developed a painless nonunion, and there was one patient with delayed union of a subtalar joint in which internal fixation was used. Gamble et al. (28) reported on 10 tibiotalar arthrodeses in eight patients using a variety of techniques. Two developed painless nonunions but continued to have bleeding episodes. There have been no early or late infections in our patients who underwent ankle fusion or in those reported by Gamble.

Because talonavicular and calcaneocuboid joint involvement is rare, primary pantalar arthrodesis has been required only twice in the OHHC series. One other case was reported in the literature (68). All three of these patients obtained solid fusions and can bear weight fully without orthoses. One tibiotalar joint replacement was performed in 1978; the patient moved away, but his brother reports that he is doing well, without pain or hemarthroses. In our opinion, the ankle and subtalar joints are better treated by arthrodesis than with prosthetic arthroplasty.

Hip

Arthropathy affects the hip less commonly than the knee, ankle, or elbow. It has two modes of onset. In childhood, rapidly progressive, severe arthropathy may result from a single hemarthrosis because of increased intracapsular pressure leading to osteonecrosis of the capital femoral epiphysis (Fig. 136.11). More often, hip arthropathy is the result of chronic synovitis, similar to that of the other joints (Fig. 136.12A). The first prosthetic arthroplasty of the hip in a hemophiliac in the United States was a cup arthroplasty performed at OHHC by J. Vernon Luck in 1968 (Fig. 136.12B).

End-stage hip disease in hemophiliacs poses a dilemma. The patients are relatively young when they require hip replacement. They are not suitable candidates for fusion because of knee involvement. In our experience, primary cemented prostheses have a 33% aseptic failure rate at 8 to 18 years follow-up, which may be higher than expected in a comparable group of patients with another form of polyarthritis. The patients in the OHHC series were relatively young (30 to 61 years of age at the time of surgery) but not particularly active owing to multicentric arthritis. Hemophiliacs tend to be slender, and none of the hip replacement patients was overweight. With the exception of periarticular cysts, bone density is better than would be expected in a group of patients with rheumatoid arthritis in the same age range. Kelley et al. (33) reported a failure rate of 21% for cemented femoral components and 23% for cemented acetabulaii, with a median follow-up of 8 years. In addition, 10 of 24

Figure 136.10. Advanced arthropathy of the ankle involving both tibiotalar and subtalar articulations. This patient has a severe equinus deformity that resulted from a massive calf hemorrhage during his adolescence, which was before clotting factor was available.

Figure 136.11. A: Frog lateral x-ray study in a 20-month-old boy with severe hemophilia B and a history of a hemarthrosis in his left hip at 6 months of age. B: The same patient at skeletal maturity. His capital femoral epiphysis never developed.

Figure 136.12. A: Advanced hemophilic arthropathy of the hip resulting from chronic synovitis with typical joint surface erosions and lateral subluxation. The coxa valga is probably the result of inhibition of abductor function from hemarthroses during growth. B: Cup arthroplasty in the same patient. This was the first major reconstructive procedure performed on a hemophilic at OHHC.
cemented femoral and 10 of 23 cemented acetabular components showed radiographic evidence of "definite" loosening. Within this group were three patients with late infection, all of whom were infected with HIV. Nelson et al. (55) reported on 22 total hip replacements, eight of which had been revised or showed definite signs of loosening radiographically, with an average follow-up of 7.6 years. There were two deep infections, but this factor was not correlated with HIV status.

A unique aspect of many patients with advanced hemophilic arthropathy is a remarkably stiff-legged gait due to severe arthrofibrosis of the knee and ankle. This causes increased forces on the hip due to a lengthened lever arm and loss of the normal shock-absorbing function of the knee and ankle. All of the patients in our series had bilateral knee and ankle arthropathy, and none had knee joint replacements. Part of the reason for loosening of cemented hip prostheses in hemophilic patients may be the increased forces of a stiff-legged gait. Another consideration is the possibility of bleeding within the membrane that forms at the cement-bone interface. As a result of subclinical hemorrhage within and around this membrane, loosening may propagate more rapidly in hemophiliacs than other arthritic patients.

Since 1982, we have used porous-coated, un cemented hip prostheses to improve durability. Results in terms of pain relief and cessation of hemarthroses have been excellent, and none of the 12 cases have required revision for fixation failure. One HIV-positive patient developed a late infection requiring prosthesis removal. More cases are needed before we will know if this represents a significant improvement over cemented prostheses in the management of hemophilic arthropathy of the hip.

**Shoulder**

Arthropathy of the shoulder deserves more attention than it has received. Shoulder pain, like hip pain, can be intractable, interrupting sleep and daytime function. Many patients lose the ability to lift the shoulder, and this loss is based on the presence of motion occurring in the rotator cuff. Since the patient is aware of a significant problem, attempts to restore range of motion and increase strength are usually thwarted by hemorrhage due to synovial hypertrophy that is friable and bleeds even with an antihemophilic factor replacement.

Chronic synovitis of the shoulder frequently resists conservative measures. Open shoulder synovectomy has been abandoned because of unacceptable loss of motion and persistent pain. Shoulder arthroscopy is severely inhibited in these joints because of fibrosis and hyperplastic synovitis. The answer to this dilemma for all hemophilic joint involvement, especially that of the shoulder, is early diagnosis by regular examination or at the time of initial hemorrhage. Early in the course of the disease, maintenance of strength and range of motion is still possible. Regular follow-up examinations are essential. Persistent synovitis, which is unresponsive to prophylactic concentrations, should be treated by synovectomy either with radiocolloids or arthroscopically before joint surface erosion and arthrofibrosis cause loss of motion.

Inexorable progression to end-stage arthropathy is the usual course. Hemarthrosis diminishes in the fibrotic end-stage joint. Pain is the primary indication for surgical intervention. Loss of shoulder motion in these patients does not cause enough impairment of activities of daily living to warrant surgery by itself. End-stage arthropathy of the shoulder may be treated by arthroplasty or arthrodesis. The traditional approach has been arthrodesis, which gives predictable and durable results but has the disadvantage of loss of motion, especially rotation. Impairment of shoulder function in most of these patients makes loss of shoulder motion even more consequential. The patient must be involved in this decision after careful counseling.

Two of the first three patients treated by shoulder fusion at OHHC obtained to solid bony union, although the clinical results were good in terms of the absence of pain and hemarthroses because of a stable fibrous ankylosis. These nonunions seem to have occurred because of reactive sclerosis at the glenohumeral joint combined with the use of single-plane glenohumeral screw fixation. Our preferred method of fusion is the three-plane screw fixation method developed by Kauko Vainio (personal communication, 1974). This method includes the AO screw transfixion of the acromioclavicular and coracohumeral junctions in addition to the glenohumeral joint. Glenohumeral and acromioclavicular wire loops lend additional stability. The upper extremity is placed in a salute position, with the shoulder in 20° to 30° of abduction, 30° of forward flexion, and 30° to 40° of internal rotation. Postoperatively, we immobilize the shoulder in a modified Bateman foam support, which allows passive elevation of the arm. In the immediate postoperative period, we are able to reach the top of the head with the help of neck flexion, and all can reach their sacrums. The five patients in whom three-plane screw fixation was used have all attained solid bony union.

Prosthetic shoulder arthroplasty has the advantage of increased rotation but does not improve abduction or forward flexion owing to the arthrofibrosis. During the last 15 years, we have performed six prosthetic shoulder arthroplasties in hemophiliacs using the Neer II prosthesis with cement fixation. All are satisfactory, and none has recurrent hemarthrosis. Five are pain free, and the other has occasional slight pain. Range of motion is improved in all compared with their preoperative status. Rotation is better than the fusion group but forward flexion and combined abduction are about the same.

**IMPACT OF HIV INFECTION ON ELECTIVE RECONSTRUCTIVE SURGERY**

It is estimated that 90% of severe, type A hemophiliacs became infected with HIV between 1978 and 1985, and the introduction of an effective antibody screen, the enzyme-linked immunosorbent assay (ELISA), in 1985. Mild and moderate type A and type B hemophiliacs use less clotting factor concentrate and thus fewer have seroconverted. This factor has added immensely to the complexity, morbidity, and mortality of an already medically challenged population. Fortunately, treatment of HIV infection has improved to the point at which patients who were severely debilitated are now stable and leading relatively normal lives. Many of these patients have advanced arthropathy and are potential candidates for reconstructive surgery.

We often are asked how the presence of HIV and acquired immune deficiency syndrome (AIDS) has affected indications for elective surgery in these patients. As always, the decision is based on the risks and benefits to the patient. No decision is made without a comprehensive team evaluation, team conference, and multiple discussions with the patient.

**Surgery.** elective or emergent, on the HIV-positive patient involves some special risks, which may be divided into two categories: risk to the patient, and risk to health care personnel. Both of these risks must be understood and considered in making a decision regarding the appropriateness of surgery for these patients. Because of concern about these issues, some orthopedic surgeons may pursue nonoperative management of fractures that are usually treated surgically and are reluctant to recommend elective reconstructive surgery in the HIV-positive patient.

Because of documented seroconversion of health care personnel following HIV-contaminated puncture injuries (8) and the frequency of parenteral and surface exposure to blood and body fluids in the operating room setting, there has been extensive study of the risks to health-care personnel. Recent reviews of methodologies to reduce this risk in the practice of orthopaedics have been developed and published by the Task Force on AIDS and Orthopaedic Surgery of the American Academy of Orthopaedic Surgeons (AAOS) (69). To date, there have been 49 well-documented occupational seroconversions among health care workers. However, none have followed suture needle injuries, the most common surgical percutaneous injury (8). In a recent report from the Centers for Disease Control (CDC), zidovudine (ZDV) was shown to be effective in the prevention of seroconversion following percutaneous exposure to HIV-contaminated blood (6,10). Hepatitis C virus (HCV) transmission by percutaneous injury may pose a greater risk to health care personnel than HIV. HCV is about equally prevalent in this patient population and is estimated to be about 10 times more transmissible by percutaneous injury (53,51,54). We believe that if the AAOS/CDC recommendations are closely followed, the risk to health care personnel, although real, can be reduced to an acceptable level.

**Risks to health care personnel can be significantly lessened but not totally eliminated by the vigorous application of universal precautions in the operating room and on the general medical ward.** In the operating room, masks, gowns, and foot covers are used; the operating room is effective for blood or body fluid contact with eyes or skin. Power equipment (e.g., saws, drills) that creates airborne droplet splash is used; we wear face suits with inflow and outflow high-efficiency particulate arrestance (HEPA) filters. Even more important than this is the prevention of puncture injuries from suture needles, bone spicules, and other sharp objects, which are common in orthopedic surgery. Modified surgical technique and the routine use of triple gloves with a cloth intermediate glove can help reduce this risk. Research is under way on the development of a tougher, more protective glove material.

In addition to concern about the risk of HIV transmission in the health care setting, surgeons have expressed concern about the complications and outcome of operations on the HIV-infected patient. This risk may be divided into early and late postoperative complications. Early postoperative complications of greatest concern in the HIV-positive patient include sepsis and impaired healing. The late postoperative complication of primary concern in the HIV-positive orthopaedic patient is implant infection. Several reports have speculated that this risk is increased (23,33). The risk of early and late septic complications is theoretically increased because of impaired cellular and humoral immunity. The estimated magnitude of increased risk is based on a series of reports of the outcome of surgery on HIV-positive patients and is less well delineated than the theoretical basis. These clinical studies also address our ability to prevent complications in the HIV-positive surgical patient successfully.

Buehler et al. (7) studied surgical wound infection rates in HIV-positive and HIV-negative hemophiliacs by reviewing 169 procedures, 53 of which were orthopaedic. There were two wound infections but no statistically significant difference in the wound infection rate between the HIV-positive group (1.4%) and the HIV-negative group (0%). There were no wound infections in the seven procedures performed on patients with AIDS.

Greene et al. (23) reviewed 26 orthopaedic procedures on HIV-positive hemophiliacs performed between 1984 and 1988. There were no surgical site infections but there was one case of cellulitis at an intravenous site. Five patients had a protracted postoperative fever but did not develop clinical infection. The outcome and functional results were similar to the patients treated before 1982 who were presumed to be HIV negative.
In a mail survey of 115 hemophilia centers, Ragni et al. (61) studied the rate of early postoperative infection in 74 orthopaedic procedures performed on 66 HIV-positive patients with CD4 counts below 200 at the time of surgery. [Cluster designation (CD) identifies lymphocyte subsets.] A CD4 count of less than 200 qualifies these patients for the diagnosis of AIDS. Eliminating those patients with evidence of active infection preoperatively, the rate of postoperative infection was 7.5%. Thirty-four of the 74 procedures were joint replacements, of which there were five postoperative infections without evidence of infection preoperatively. Except for the timing of infection, this rate of 6.7% is not different from reported series of joint replacements in HIV-negative hemophiliacs (21,43,53).

RECOMMENDATIONS FOR SURGERY ON THE HIV-POSITIVE PATIENT

Based on current basic and clinical knowledge, a general philosophy or guideline may be developed for elective surgery on the HIV-positive hemophiliac patient in various stages of disease. Most of the clinical studies available to date do not demonstrate an increased incidence of early postoperative complications in asymptomatic HIV-positive patients compared with the HIV-negative group. Furthermore, most of the orthopaedic studies and the more recent general surgery studies do not show an increased incidence of early complications in the symptomatic HIV positive patients with CD4 counts above 200 undergoing elective procedures. The basic science work establishes some impairment of defenses against common orthopaedic pathogens and the potential delay of wound healing (45). As the disease progresses and these impairments increase, the hazard of early complication increases. The risk of late prosthetic implant infection is increased in hemophiliacs regardless of HIV status. In view of all of these factors, special management of the HIV-positive hemophiliac patient undergoing surgery seems warranted. OIHC uses a protocol that serves as the basis for the following recommendations.

Informed decision making about the advisability of surgery is crucial. As a result of improved reverse transcriptase agents and third-generation protease inhibitors, high viral loads are treatable to undetectable levels, often resulting in elevation of the CD4 count. The prognosis and life expectancy for patients with AIDS has improved dramatically, making reconstructive surgery in these patients who require it an appropriate consideration. Following a thorough assessment of the patient's medical status, a thoughtful discussion of the risk-benefit ratio ensues between the patient and the multidisciplinary team. Quality of life issues are often a principal consideration in the patient's view and must be balanced against risk management.

The spectrum of disease in HIV infection is a continuum on which each patient may be positioned to assess risk properly. No single clinical factor is a reliable predictor of longevity or risk of surgery. Several components should be combined in determining a prognosis and assigning risk. The factors that seem to correlate best with surgical outcome are history of opportunistic infection, CD4 cell level less than 200, serum albumin less than 25 g/L, and cutaneous anergy (43,61). However, these studies indicated current HIV therapy. Today, viral load combined with CD4 counts are the primary indicators for surgery. Patient reliability and ability to cooperate with medical recommendations is essential to reduce the risk of late complications in the joint-replacement patient.

Once a decision is made to proceed with surgery, several steps can be taken to reduce the risk of perioperative complications further. Some of the measures are applicable to an emergent situation. Others require more time and are only feasible in elective surgery. The absolute polymorphonuclear leukocyte count should exceed 1,000 and the platelet count should exceed 50,000. In addition to HIV, platelet deficiency can result from chronic active hepatitis B or C, which is common in hemophiliacs, and may vary from 30,000 to 60,000, depending on liver function status and other comorbidities. Platelet transfusions also may be used when needed. Chronic liver disease can also reduce vitamin K levels, which can further compound the coagulation disorder. In patients for whom surgery is essential, granulocyte-stimulating factor may also be used to elevate an unacceptably low white blood cell count. Low platelet and white blood cell counts may be indications that management of the patient's underlying infection with HIV or HCV, or both, is inadequate, which should be corrected before any elective surgery. Inadequate management may be an indication of patient noncompliance, which will place the patient in a higher risk category for postoperative complications if it cannot be reliably corrected. All patients should be carefully screened for opportunistic infections, including bacterial, mycobacterial, and fungal agents that might increase the risk of early or late postoperative infection.

Many of the symptomatic HIV-positive patients are chronically anemic as a consequence of disease and therapy, and may require transfusion before surgery. Clinically appropriate, marrow-suppressing drugs should be stopped a few days preoperatively and resumed after the first postoperative week. Some of the drugs used to suppress HIV, such as ZDV, didanosine (DDI), and zalcitabine (DDC), can cause various degrees of marrow suppression. However, the more recently developed reverse transcriptase inhibitors such as lamivudine (3TC) and stavudine (D4T) and the protease inhibitors are not likely to do this. Prophylactic antibiotics seem clearly indicated in this patient population. In the patients with advanced HIV infection, some authors have suggested continuation of prophylactic antibiotics longer than normal, but there are no data to demonstrate efficacy, and many studies show no increase in the incidence of early postoperative infection in this patient population.

The HIV-positive patient with a prosthetic implant may be at increased risk of late hematogenous implant infection as host defenses diminish. Patients are cautioned to follow-up closely after an initial bleed. The role of radiosynovectomy versus arthroscopic synovectomy is being defined. When end-stage arthropathy does occur and is severe, durable, functional reconstruction with minimal risk must be our goal.

CHAPTER 137

BIOMECHANICS OF SPINAL INSTRUMENTATION

Christian M. Pullitz, Vijay K. Goel, and Robert F. McLain

The spine is a mechanical entity. Its most important function is to protect the spinal cord from damage while allowing physiologic motions at each vertebral level. Many times, especially in disease states or in the case of trauma, vertebral motion may produce impingement on the spinal canal, resulting in elevated pressure on the spinal cord. Some spinal disorders may reduce mechanical stability, resulting in abnormal motion, pain, or deformity in the face of normal loads and activity. The primary goal of surgical intervention is to relieve extraneous spinal pressure, reduce the patient's pain, and obtain correct spinal alignment.

Obtaining a solid fusion of the affected levels is often the long-term goal of surgery. It is commonly achieved by open reduction and bone grafting, with the postoperative reduction maintained by fixation implants. Each stage in treatment has an associated biomechanical implication that cannot be overlooked.

NORMAL MOTION

The normal motion of the spine is determined by the spinal structures, particularly the facet joints and intervertebral disc. The spine exhibits two types of motion: in-plane and "coupled" motion. Coupled motion is defined as movement that is out of the plane of the applied loads. The orientation of the facet joints primarily determines the magnitude of in-plane and coupled motion.

Range-of-motion (ROM) characteristics are determined partially by the intervertebral disc and ligaments. Hyperextension, for instance, is limited by the anterior longitudinal ligaments and the anterior portion of the annulus fibrosis. Flexion is limited primarily by the posterior ligamentous complex and capsules of the facet joints. The degree of lateral bending is usually checked by the capsular ligaments and facet joints. Axial rotation is regulated by the intervertebral discs including Luschka's joints (cervical spine), facet joints, and capsular, interspinous, and supraspinous ligaments. It has been demonstrated that 90% resistance to axial rotation in the lumbar spine is provided by the facet joints and intervertebral discs; the ligaments are responsible for the remaining 10%.

The upper cervical region, the occipitoatlantoaxial complex (C0–C1–C2), is the most mobile area of the spine (Fig. 137.1). Both the occipitoatlantal and atlantoaxial levels allow greater than 20° of flexion and extension. Also, the C1–C2 facets and the atlantoaxial articulation allow for 40° to 50° of axial rotation to each side. The lower cervical spine (C3–C7) exhibits more lateral bending than the occipitoatlantoaxial complex. Sagittal plane and axial rotation diminish from the C4–C5 level and below.

Because of its articulation with the rib cage, the thoracic region is the least mobile portion of the spine. The upper thoracic spine allows significant axial rotation (approximately 10°), but below T8–T9, the major motion of the thoracic spine is in flexion and extension. The lumbar spine permits a significant degree of flexion and extension across all levels. There is a sharp increase in the amount of lateral bending exhibited by the L3–L4 level, with a corresponding decrease at the L2–L3 and L4–L5 motion segments. Axial rotation in the lumbar spine is limited by the vertical orientation of the facet joints.

INSTABILITY

Measurement of spinal stability (or instability) is integral to the diagnosis and treatment of the lumbar spine. Instability of the spine can be a result of a purely mechanical disorder or a disorder of another origin. Incorrect judgments of spinal stability can lead to unnecessary surgery in some cases or inadequate treatment in others. Unrecognized and untreated instability exposes the patient to an increased risk of neurologic injury, pain, and in the upper cervical spine, mortality. White and Panjabi define clinical instability as “the loss of the ability of the spine under physiologic loads to maintain its pattern of displacement so that there is no initial or additional neurological deficit, no major deformity, and no incapacitating pain.” The key phrase within this definition, for the purpose of understanding stability, is “to maintain its pattern of displacement.” Trauma, degeneration, and certain clinical procedures can severely alter the spine's normal pattern of displacement and lead to instability.

A checklist based on clinical and radiographic criteria has been developed to help the physician determine the degree of instability; see Table 137.1. (43) Radiographs of the spine are taken, whereupon the physician assigns a certain number of points depending on range of motion and condition of spinal elements. According to this system, a total of five points or more indicates a clinically unstable spine.
Most often, spinal instrumentation systems are described in terms of where the hardware is attached: anterior, posterior, or interbody. As instrumentation procedures have become increasingly popular, motion between the affected segments increases the likelihood of fusion and may reduce the degree of pain the patient experiences. Extensive disc removal at the time of surgery can lead to a 14% increase in flexion, a 38% increase in lateral bending, and a 62% increase in axial rotation. Partial or complete removal of these vertebral elements would result in an unstable spine. In fact, however, partial unilateral or bilateral laminectomy has a greater effect on the amount of flexion and axial rotation (approximately a 15% to 20% increase) than lateral bending (less than a 5% increase). Nerve damage can upset the normal distribution and transmission of loading, leading to further instability. Thus, it is necessary to describe the biomechanical effects due to partial or complete spinal element removal. The three most common procedures involving spinal element resection are laminectomy, facetectomy, and partial or complete removal of the intervertebral disc.

Laminectomy involves partial or complete removal of the posterior vertebral arch to decompress the neural elements, cord and nerve roots. Partial laminectomy does not necessarily result in instability. Cadaver experiments show that partial laminectomy has a greater effect on the amount of flexion and axial rotation (approximately a 15% to 20% increase) than lateral bending (less than a 5% increase). Controversy exists as to whether fusion is necessary following laminectomy procedures. Degenerative spondylolisthesis cohort studies suggest that laminectomy with fusion results in a decrease in pain, with increased stability. However, follow-up studies on patients who had laminectomies for spinal stenosis showed no difference in outcome whether or not a coincident fusion procedure was performed. It appears that an indication for fusion depends more on the evidence of pre-existing instability than on the decompression itself.

The geometry of the posterior facets is important in determining the relative amount of motion at each spinal level. In particular, the facets serve to resist axial rotation and extension motion. Farfan et al. demonstrated that, in the lumbar region, the facets alone resist approximately 50% of the torsional loads experienced by the spine. It would seem intuitively that partial or complete removal of these vertebral elements would result in an unstable spine. In fact, however, partial unilateral or bilateral facetectomy at one level results in greater motion but may not produce instability. Complete facetectomy (unilateral or bilateral) increased motion by 78% in extension, 63% in flexion, 15% in lateral bending, and 126% in axial rotation as compared with the intact controls, confirming that the degree of instability can be directly correlated with amount of facet removal. Intervertebral disc disorders can produce instability. The intervertebral disc can degenerate, becoming dehydrated and fissured, resulting in nonphysiologic loading. The nucleus pulposus can evidence fibrous tissue formation, leading to nonhomogeneous stresses evident the disc. The intervertebral disc, which may protrude or herniate, causing nerve root compression, has been implicated as common source of low back pain ("discogenic pain"). Thus, many surgical interventions involve removing part or all of an intervertebral disc, as do interbody fusion techniques.

Partial removal of the disc can lead to isoteric instability. It has also been shown that disectomy with minimal removal of the lamina does not produce instability. In fact, complete disectomy (partial laminectomy, partial facetectomy, partial annulus removal, and complete nucleotomy) results in an 80% increase in flexion, an increase of 60% in extension, a 38% increase in lateral bending, and a 62% increase in axial rotation. Postdisectomy back pain may be associated with more extensive disc removal at the time of surgery.

A theory that has gained some popularity in assessing spinal instability involves the idea of quantifying the "neutral zone". Within the neutral zone, there is minimal resistance to intervertebral motion; minor changes in load result in considerable shifts in position. A patient in pain may reveal an increase in the neutral zone, allowing motion to occur beyond the pain-free zone under physiologic loads, while showing no change in the spine's overall range of motion. In contrast, when the spine is stabilized, pain may decrease because of a decrease in the range of the neutral zone as well as the overall range of motion.

At present, clinicians can quantify the degree of instability within the lumbar spine through the use of magnetic resonance imaging (MRI), computed tomography (CT) scans, and radiographs, which can indicate the spine's range of motion. (Take care to identify whether the data are based on active or passive range of motion, because there is a difference between the two.) Many recent studies have also postulated that a measurement of the time course of motion within the spine may be as important as range of motion in determining degrees of instability. How much each one of these factors contributes to the speed at which the patient moves is unknown. No conclusive evidence has indicated that velocity measurements are more sensitive to motion than ROM measurements. The large amount of variability found in static patient movement for diagnostic purposes has limited the clinical usefulness of such measurements. Therefore, a dynamic analysis of the spine should be used as a supplement to static radiographs for the determination of spinal instability; flexion and extension x-ray studies are the most widely used studies for this purpose.

Spinal instability can be the direct result of trauma, degeneration, tumor, infection, muscle dysfunction, surgical intervention, or any combination thereof. Damage to any portion of the functional spinal unit (vertebra-disc-vertebra assembly) can lead to instability. The most important spinal elements contributing to instability are the intervertebral disc, facet joints, and the perispinal ligaments. It is often necessary to dissect some or all of these components during spinal surgery. Just exposing the spine can damage fine nerves that contribute to muscle function and coordination. Jerky movements may be indicative of a lack of fine motor control. Some studies suggest that the dynamics behind the movement of the spine are subject to a great amount of variability depending on neuromuscular coordination, motivation, skill, physiologic strength and flexibility, and metabolic support.

How much each one of these factors contributes to the speed at which the patient moves is unknown. No conclusive evidence has indicated that velocity measurements are more sensitive to motion than ROM measurements. The large amount of variability found in static patient movement for diagnostic purposes has limited the clinical usefulness of such measurements. Therefore, a dynamic analysis of the spine should be used as a supplement to static radiographs for the determination of spinal instability; flexion and extension x-ray studies are the most widely used studies for this purpose.

Sagittal plane displacement greater than 4.5 mm or 15% of the anteroposterior diameter of the vertebral body or relative angulation greater than 22° denotes potential instability (45,50). Also, relative sagittal rotation greater than 15% at L1–L2, L2–L3, and L3–L4; greater than 20° at L4–L5; or greater than 25° at L5–S1 represents an abnormal range of motion and potential instability (54). The presence of a neurologic deficit is also diagnostic of spinal stability.

FUSION AND INSTRUMENTATION

Spinal stabilization and fusion procedures have been used to treat ailments ranging from fractures and tumors to spondylolisthesis and disc degeneration. Eliminating motion between the affected segments increases the likelihood of fusion and may reduce the degree of pain the patient experiences. Properly applied, spinal instrumentation maintains alignment and shares spinal loads until a solid, consolidated fusion is achieved.

As instrumentation procedures have become increasingly popular, the number of available fixation systems has grown. With few exceptions, these systems are used in combination with bone-grafting procedures and may be augmented by external bracing systems.

Most often, spinal instrumentation systems are described in terms of where the hardware is attached: anterior, posterior, or interbody.

- The "anterior" devices such as anterior plates and screw systems usually are classified as those systems that are designed to attach to the anterior or anterolateral aspect of the vertebral body. Typically, the plate or rod construct is transfixed to the involved vertebral segments by screws that pierce one or both cortices as well as gain purchase in the cancellous bone of the vertebral body.
- "Posterior" systems are affixed to the elements situated posterior to the vertebral body, the spinous processes, pedicles, facets, or laminae. These instrumentation systems use laminar hooks, pedicle screw systems, facet screws and wiring techniques.
- Finally, interbody fusion systems promote fusion between the vertebral bodies by the incorporation of a device or graft that spans the disc space. Although allograft and autograft spacers are routinely used in combination with other anterior or posterior instrumentation, a variety of "stand-alone" devices are now available and approved for implantation. Usually, the interbody systems are further classified by the surgical approach used during device implantation. The corolling of system and approach has given rise to such contemporary terminology as anterior lumbar interbody fusion (ALIF), transforminal lumbar interbody fusion (TLIF), and posterior lumbar interbody fusion (PLIF) procedures.
POSTERIOR DEVICES

The earliest form of spinal fusion was developed using the posterior fusion technique. The concept originated using the midline fusion technique wherein the graft material spanned adjacent spinous processes and lamellae (Fig. 137.24). This technique is biomechanically disadvantageous. The graft material is situated far from the center of rotation and experiences tensile forces when the spine is put in flexion, both factors that may induce excessive motion and cause the graft to migrate before it can incorporate and consolidate. The measured stress increases as the distance from the center of rotation increases; thus, grafts placed at this distance may result in a nonunion due to resorption or material failure. In addition, tensile loads experienced by the graft also may cause it to fail because bone is inherently more stable in compression than in tension. The clinical outcome is delayed union or nonunion.

Figure 137.2. Schema depicting two types of posterior fusion devices. A: The Luque Loop application is a midline procedure that uses wiring to achieve fixation to the spine. B: The posterolateral application of Steffee plates involves pedicle screw fixation (From Goel VK, Lim TH, Gwon J, et al. Biomechanics of Fusion. In: Andersson GB, McNell TW, eds. Lumbar Spinal Stenosis. Chicago: Mosby-Year Book, 1996:403, with permission.)

These mechanical disadvantages were manifested in the relatively high pseudoarthrosis rate with early posterior fusion techniques. The most commonly employed contemporary method of fusion, the posterolateral fusion technique (Fig. 137.26), addresses many of these flaws. The posterolateral technique involves fusion of the transverse processes and the facet joints of adjacent vertebrae. The intertransverse fusion allows placement of the graft in closer proximity to the center of vertebral rotation than the midline fusion, thus reducing the tensile loads experienced by the graft and decreasing the risk of graft migration.

Both factors increase the probability of obtaining a solid fusion. Although aggressive removal of the facet cartilage does reduce the inherent stability of the motion segment, the increased surface area for fusion and close apposition of the facet joint surfaces facilitates the rate of fusion. Internal fixation using wiring, pedicle screw fixation, and hooks usually reduces the risk of graft displacement by decreasing displacement and the loads through the graft during the healing process.

Posterior implant systems have evolved from simple distraction devices, using hooks to force the laminae apart and straighten the spine. Sublaminar wires were the first implant used to provide “segmental” fixation, attaching the rod to the spine at multiple points along the length of the construct. They are still used in deformity surgery, but because they do not provide axial stability, they are a poor choice for stabilizing fractures or bone loss due to tumors. Sublaminar wires have greater leverage in directly pulling the displaced element to the correcting rod than the distraction systems could safely generate, but they cannot prevent these elements from sliding down the rod should adjacent levels collapse.

Contemporary segmental systems use a variety of hooks to attach to multiple points along the construct, and they offer a means of locking the hook to the rod at any given point to maintain axial distraction or compression forces after implantation. Pedicle screws, large fixation screws implanted through the lamina and pedicle into the vertebral body, allow segmental fixation even in areas where the laminae have been removed. Pedicle screws are the only devices available that provide fixation to all three vertebral columns. When used in combination with sublaminar wires and pedicle screws, contemporary posterior instrumentation systems are highly versatile and effective devices.

Pedicle screw systems in particular continue to gain use. These systems provide a high degree of construct stability as well as afford good fixation to the spine. Because pedicle screws are inserted into the vertebral body, these posterior devices can directly manipulate the intervertebral space. Pedicle screws also allow one to apply distraction, compression, lordosis, rotation, and anterior or posterior fixation forces selectively. They are the most important factor that provides torsional stiffness in thoracolumbar spinal constructs. Pedicle screw systems provide a means to treat thoracolumbar instability after burst fracture or resection of a spinal tumor. However, they must be augmented with anterior column support to avoid exposing the screws to excessive cantilever loads that might cause bending failure or breakage.

As the indications for the use of pedicle screw systems have increased, additional modifications have become essential to increase their effectiveness and compensate for the shortcomings of the system for a given indication. For example, studies reported a high rate of screw failure when first-generation screws were used to treat thoracolumbar burst fractures (39). Implant failure, by either acute bending failure (postyield deformation) or acute fracture, was seen in young patients with axial instability due to trauma. Screw failure contributed to loss of alignment and fixation. Loosening, toggling, or backing out of the screw owing to failure of bone may occur, early or late, in older patients with weak, osteoporotic bone.

Fatigue failure, occurring after the bony healing period, often results in asymptomatic screw breakage and is usually not a problem clinically. To reduce screw-bone interface problems, augmentation of thoracolumbar constructs with offset laminar hooks has been recommended (53). Laminar hooks help decrease the load transmitted between the bone and pedicle screws, thereby protecting the screws and the bone. Injection of bone cement in the hole before insertion of the screw has also been suggested to increase the bone–screw interface strength, but this approach has limited effectiveness in severely osteoporotic patients and introduces some very real, uncommon risks.

Clinical failure in pedicle screws occurs two ways—by loosening and fixation failure and by acute or subacute bending failure or breakage. Loosening occurs as repetitive loading persists beyond the tolerance of the bone, which is usually due to delayed union or excessive activity. The screw is exposed to a combination of cantilever bending and axial pullout loads. Cantilever bending loads may also exceed the yield point of the screws, resulting in acute bending failure and breakage. Even in the degenerated and collapsed disc, axial loads impart small cyclic displacements that generate significant cantilever displacements. These generate more pronounced around the screw hub, inside the pedicle. When the pedicle screws are forced to bear most or all of the anterior column's axial loads, as in burst fracture or tumor reconstruction, excessive bending moments predictably lead to screw failure and progressive kyphosis.

ANTERIOR DEVICES

The advantage of the anterior approach to the spine is that it gives direct access to the area of disease, which is frequently the disc or vertebral body. The anterior approach allows the surgeon to decompress the neural structures, resect the disease, reduce deformity, and stabilize the injured segment. Fusion anteriorly has the mechanical advantage of being in closer proximity to the vertebral center of rotation, thus reducing the stresses on the graft and hardware, as well as being placed in compression.

Anterior reconstructions directly oppose the greatest forces acting on the thoracic and thoracolumbar spine—the anterior compressive forces generated by gravity, posture, activity, and muscular contraction. Unopposed, these forces lead to progressive and disabling kyphosis. Whereas posterior systems depend on long lever arms and cantilever forces to resist kyphotic collapse, anterior struts are loaded in nearly pure compression, the cortical bone's strongest aspect. Anterior instrumentation need only share the compressive load and resist translation and torsion to be effective.

Biomechanical animal studies (59) have demonstrated the efficacy of obtaining a solid fusion when anterior instrumentation is used. These studies also indicate that fusion mass consolidation is greater when anterior instrumentation is used, resulting in higher torsional stiffness of the fused levels. Most anterior fixation systems use screws placed into the vertebral body with rods or plates, or both (Fig. 137.3). The weak link in these constructs is most often the bone–screw interface, or fatigue failure of the implant occurs due to nonunion.
Although rigidity of the implant seems to be the most important feature associated with immediate postoperative stability, the higher stiffness fixation systems can, in time, impart paralytic deleterious effects. "Stress shielding" is a phenomenon that occurs with both anterior and posterior devices when a relatively stiff implant bears a disproportionately large amount of physiologic loads compared with the host bone. The biologic response of the bone to the reduction in load is resorption of the bone around the implant.

Stress shielding of the graft and surrounding bone by the implant can lead to progressive angular deformities and loss of fixation of the implant to the bone owing to weakening or resorption of the bone around the implant, which leads to migration of the implant in the bone. More rigid fixation, however, has been associated with greater degrees of immediate postoperative stability. Thus, the dilemma is that although higher implant rigidity is needed in the immediate postoperative period, it may contribute to stress shielding as time proceeds.

The clinical importance of stress shielding in any given construct remains unclear. Additionally, the controlled subsidence of the graft into the vertebral endplate may be a contributing factor to successful fusion, which stiffer implants may impair. At the extreme, resorption of the graft adjacent to a rigid implant may convert a "load-sharing" device to a "load-bearing" device, leading predictably to implant failure.

To overcome these perceived deficiencies, several new devices of more flexible design have come on the market (48). The flexible devices theoretically permit more load-bearing through the interbody bone graft. They may not, however, provide the same degree of immediate stability until fusion occurs. In newer implants the rigidity of the device decreases as a function of time, providing a rigid construct for the initial healing phase and thereafter permitting larger loads through the fusion site because of a gradual decrease in the rigidity of the device (29). The newer anterior as well as posterior "dynamized" systems seek to allow a preset degree of axial subsidence due to graft resorption and settling, thereby allowing temporal load-sharing as graft consolidation proceeds (28). These devices are quite new, however, and are still in evaluation and thus not accepted for general use.

INTERBODY FUSION DEVICES

Total disc removal alone or in combination with other surgical procedures invariably leads to a loss of disc height and an unstable segment. Both allografts and autologous bone grafts have been used as interbody spacers. Autogenous bone grafts have the disadvantage of donor site morbidity, and both autografts and allografts are subject to dislodgement when used anteriorly, resulting in loss of alignment.

The use of disc space inserts fabricated from synthetic materials has gained popularity. These inserts may be implanted through an anterior or posterior approach. Interbody cages composed of titanium or carbon fiber mesh promote fusion by imparting immediate postoperative stability, promoting fusion through the incorporation of bone chips packed inside the cage (25). Anterior procedures used to implant cages usually require extensive removal of the anterior portion of the annulus fibrosis and anterior longitudinal ligament. The strength of the construct relies in part on distraction, which produces tension in the remaining annulus (13).

Posterior interbody fusion procedures require removal of various posterior elements. Iatrogenic or acquired (spondylolytic) posterior column instability frequently requires posterior fixation. Combined anterior or posterior interbody fusion and posterior instrumentation and fusion in the lumbar spine usually requires partial or complete facetectomy, removal of the pars interarticularis, and partial or complete discectomy. These constructs require a significant amount of load-bearing by the graft and (and cage) construct and posterior hardware to resist translation and torsion forces (47).

BIOMECHANICAL EVALUATION OF INSTRUMENTATION AND DEVICE FAILURE

The development of various spinal devices has come, in large part, from a desire on the part of surgeons to improve success rates. The operative assumption is that better instrumentation will produce better surgical results, whether success is defined in terms of fusion rate, correction of deformity, pain relief, or hardware survival. Thus, it is no surprise that the engineering community, in concert with surgeons, is constantly evaluating the mechanical performance of spinal instrumentation.

Over the years, a vast number of biomechanical studies have appeared in peer-reviewed journals publishing data on a multitude of clinically relevant mechanical parameters, collected using an equally large and diverse number of in vitro and in vivo testing methods. The literature can be loosely divided into several distinct categories that outline the stepwise evolution that typically occurs in the design and development of spinal implants and subsequent release for clinical use (1,2,13,46).

Stiffness is the ratio of the applied load to the resultant displacement. The failure load defines the maximum load that can be applied to the construct before component or fixation failure occurs. Fatigue load is usually defined as the number of loading cycles, at physiologic loading levels, that can be applied to a given system before hardware or fixation failure.

The goal of most instrumentation systems is to minimize motion between the affected levels: thus knowledge of the construct stiffnesses in flexion, extension, lateral bending, and axial rotation is requisite for a complete understanding of a particular hardware system. Load-to-failure studies reveal how the implant is likely to behave when it is first applied. Fatigue studies give insight into the likelihood and type of failures to be expected when the system is exposed to normal loads over time. Several important categories of biomechanical testing modalities illustrate the nature and value of data obtained from each study type.

1. Interconnection testing of spinal instrumentation systems has become increasingly more common, owing to the complexity of contemporary designs. This type of testing seeks to characterize mechanically the slip and failure properties of the various interfaces within the device (Fig. 137.4). Interconnection testing performed for pedicle screw and rod systems can assess the failure load needed to produce appreciable slip at the screw-rod junction.

Figure 137.3. An example of an anterior instrumentation device (applied to a cadaveric specimen). This device (ALC dynamized system, AcroMed, Inc., Cleveland, OH) uses screws driven into the vertebral body with bars spanning between the screws. These devices are commonly used in conjunction with vertebrectomy procedures.

Figure 137.4. Interconnection testing seeks to characterize mechanically the interfaces within an assembled device. Pictured are two examples: testing of the...
2. Plastic vertebrae (simulated corpectomy) models are tests that mimic the performance of fixation devices under the worst possible clinical scenario, which is where an anterior gap is produced by vertebrectomy. Tests using plastic models standardize the bone-screw interface and, thus, highlight the performance of the assembled device as distinguished from the bone-screw interface. The devices are mounted onto molded plastic vertebral components (Fig. 137.6) and subjected to axial compression, compression-flexion bending, and torsional modes, loading either statically or cyclically (fatigue testing).

Results show that most devices fail at up to 50% less load, when fatigue tested to 5 million cycles, as compared to the loads they can withstand when loaded statically (22). Failure always seems to occur at points of stress concentration, such as attachment of the rod to the screw, at threads in the rod, at the junction of the cross-links, and in the longitudinal members. These failure patterns are supported by pedicle-screw loading studies.

One such study (56) demonstrated that the maximum stresses are seen near the hub of the screw and decay nonlinearly to zero at the screw tip. Additionally, the stress concentrations introduced by the geometry of the screw hub–shaft junction increased the stresses experienced by the screw such that the screw would be at risk of fatigue failure. Biomechanical studies using analog models have shown that even small changes in screw orientation or insertion technique can affect screw bending moments (35, 36) and (37). Thus, it seems that with the development of more versatile pedicle screw systems, the clinical ease for implanting the devices may improve but may introduce additional stress concentration sites. This type of testing clearly shows the need for coordination between implant design engineers and clinicians to ensure that the likely locations of failure will be the least problematic.

Tests of the compression strength of cortical and cancellous bone dowels and cortical femoral rings, inserted between plastic blocks having matching geometry and loaded in axial compression using a servohydraulic testing machine, have shown that fresh human cancellous bone fails at an average load of 863 N, whereas cortical bone dowel strength may exceed 24,000 N (4). The assembly depicted here is being subjected to a combined loading of flexion and compression.

One of the failures seen in these tests is the pullout of instrumentation components from the bone (Fig. 137.7). Hook augmentation to screw fixation decreased the bending moment experienced by pedicle screws by approximately 30%, leading to reduced screw stress concentrations introduced by the geometry of the screw hub–shaft junction increased the stresses experienced by the screw such that the screw would be at risk of fatigue failure. Biomechanical studies using analog models have shown that even small changes in screw orientation or insertion technique can affect screw bending moments (35, 36) and (37). Thus, it seems that with the development of more versatile pedicle screw systems, the clinical ease for implanting the devices may improve but may introduce additional stress concentration sites. This type of testing clearly shows the need for coordination between implant design engineers and clinicians to ensure that the likely locations of failure will be the least problematic.

This type of testing clearly shows the need for coordination between implant design engineers and clinicians to ensure that the likely locations of failure will be the least problematic.
For example, a cadaver study \(^{28}\) was used to compare the load-deformation characteristics of three different anterior devices: the Synthesis Anterior Thoracolumbar Locking Plate (ATLP, Synthes, Paoli, PA), the AcroMed Smooth Rod Kaneda System (SRK, AcroMed Corp., Cleveland, OH), and Z-Plate (Sofamor-Dane, Inc.). Loads of 0 to 6 Nm were applied in increments of 1.5 Nm to thoracolumbar spine segments from T9–L3. Following destabilization by L-1 corpectomy and removal of the adjoining discs, a wood dowel was placed between the T-12 and L-2 vertebral bodies to simulate the presence of an interbody bone graft to restore bony alignment and height.

Results showed that the SRK device provides greater stiffness than the ATLP, although it is different from the intact spine (Fig. 137.64). The Kaneda rod system provided the highest degree of immediate stability, which should provide the best chance of fusion. The stiffness of the construct obtained with the SRK and ATPL systems were equivalent to the intact spine. The SRK and Z-Plate systems withstood best fatigue loading in 5,000 cycles of flexion and extension (Fig. 137.86). The data show that the SRK and Z-Plate system will maintain their structural integrity in the face of repeated physiologic loading, thus reducing the chance of failure. Most important, the stability of construct using existing anterior devices can, at best, only approach that of the intact spine.

In flexion and extension, rigid posterior devices provide a 70% reduction in motion across the L4–L5 level, compared with the intact spine. Similar results were obtained for three different systems which were loaded in lateral bending and axial rotation as well. \(^{27}\)

Pedicile screw systems are effective, at least initially, in stabilizing the motion segment, irrespective of screw size, implant shape, or other variables. This finding is not surprising in that stainless steel and titanium implants are many orders of magnitude stiffer than the bony and ligamentous components of an intact spine. As a result, slight variations in the shapes and sizes of pedicle screw devices are not likely to affect the stability of constructs to any significant degree.

Flexible restraints have been tried. The Graf system is an extreme example of a flexible posterior system, in which bilateral polyester tension bands span the vertebral pedicle screws (51). After laminectomy, this system restored axial rotation to normal stiffness levels. It also significantly decreased the range of motion in flexion and extension and lateral bending. Flexible systems have not proven successful in restoring stability to a severely destabilized spinal segment such as after partial or total discectomy.

The major concern with dynamized systems is whether they can impart initial rigidity comparable to that of traditional systems using plates, bars, and screws. Hitchon et al. \(^{28}\) evaluated the stiffness properties of one such anterior dynamized system, the Anterolateral Controlled Compression (ALC) device (AcroMed, Cleveland, OH). The implant can be applied as a dynamized device (ALC) or can be attached rigidly (ALCR). Both applications produced the same degree of stiffness in flexion, extension, lateral bending, and axial rotation (Table 137.2). There seems to be no loss of immediate stability using the implant as a dynamized device, which may reduce long-term, deleterious effects due to stress shielding.

In a similar study \(^{49}\), this group compared the Segmental Spine Correction System (SSCS), which is a pedicle hinged screw-rod system (Osteotech, Inc. Eatontown, NJ), with its equivalent rigid screw system. The hinged screw allows 15° of movement, at which point the hinge mechanism engages the screw shaft; it then behaves like a rigid screw. The researchers showed a 65% reduction of motion in flexion and extension and 90% reduction in lateral bending across the destabilized segment for both devices when compared with the intact spine.

Interbody fusion cages have also been mechanically evaluated using cadaver models \(^{42,52}\). Nibu et al. \(^{42}\) studied the stabilizing effect of implantation of the BAK (Spine Tech Inc., Minneapolis, MN) interbody fusion device in human lumbar-sacral specimens (L5–S1). They found that range of motion was reduced by 46% in flexion, 66% in lateral bending, and 40% in axial rotation after implantation of the device as compared with the intact spine. However, extension range of...
motion increased by 14% after implantation of the device owing to the anterior approach, which required cutting the anterior longitudinal ligament and the anterior annulus, which compromises the stability in extension.

5. **Analytic modeling** (15–19), such as finite element (FE) analysis, is a valuable tool for determining how implant and intraosseous loading patterns change with varying parameters of the device design. FE modeling can also help predict bone remodeling in response to the implant; therefore, it helps in evaluating stress shielding. Goel et al. (13) have generated osteoligamentous one-segment (L3–L4) and two-segment (L3–L5) FE models of the intact lumbar spine. Using the L3–L4 model, they simulated bilateral fusion using unilateral and bilateral plating, and measured the magnitude and position of internal stresses in bone, ligament, and the implants. They normalized their data to an intact model. Bilateral plating models showed significantly reduced stresses in cancellous bone. In a simulated consolidated fusion mass, there was unloading of the cancellous bone, even after simulated removal of the device. This model predicts that removal of the fixation would not alleviate stress-shielding–induced osteopenia, which may be due to the fusion mass itself.

Models of unilateral plating revealed higher initial trabecular bone stresses than were seen with bilateral plating. However, the degree of initial stability was reduced. Thus, the best appears to be a fixation system that allows the bone to bear greater load as fusion proceeds, which would offer higher initial stability and yet minimize the problem of long-term stress-shielding–induced bone resorption.

FE modeling (17) of newer dynamic fixation systems shows that the load through the bone graft increases 10% compared with the rigid systems. Thus, it seems that the competing criteria can, in some part, be simultaneously satisfied with these dynamized devices. FE modeling coupled with bone remodeling algorithms has been used to predict temporal changes that may be associated with interbody fusion devices. Grosland et al. (25) studied the BAK device (Fig. 137.9) and showed that implantation of this interbody fusion device results in hypertrophy of bone directly overlying and underlying the implant, whereas lateral atrophy occurs due to the stress-shielding effects associated with the relatively high stiffness of the implant. The model also predicts that bone would be stimulated to grow into and around the larger holes in the implant, resulting in sound fixation of the device.

![Figure 137.9. Finite element (FE) modeling has proved to be an invaluable tool for determining the changes in load sharing associated with device implementation. The schematic depicts the implantation of an interbody fusion device into a three-vertebrae FE model. This model has been used to characterize not only the loading changes that will occur immediately in the postoperative period but also as consolidation of the graft proceeds.](image)

The value of FE modeling is that mapping of the stresses and strains in bone, ligaments, and instrumentation can be obtained in a relatively inexpensive and time-efficient manner. In addition, it yields important predictive data concerning temporal changes in bone in response to implantation of a device. It also facilitates quick assessment of the relative advantages and disadvantages of design iterations. Actual mechanical testing of constructs is still necessary, from time to time, to validate theoretical assumptions and confirm FE predictions.

6. **Animal studies** provide real-time in vivo data concerning the performance and associated biologic response to an implant. Temporal changes in both the host biologic tissue and associated instrumentation can be assessed with selective intermittent sacrificing of the animals. The usefulness of these tests is best illustrated by the animal studies performed by McAfee et al. (32–33). They investigated the effects of instrumentation on fusion consolidation and peri-implant bone density in 63 canines. The data confirmed a higher probability of achieving fusion when instrumentation was used. Mechanical testing of the fusion sites after sacrifice (and removal of all metal components) revealed that fusions achieved with instrumentation were more rigid than those that occurred without instrumentation. There was, however, an inverse correlation between volumetric density of bone and rigidity of the implant, implying that utilization of the implant resulted in an osteoporotic effect owing to stress shielding. These findings could not have been predicted by the FE models available at the time.

The findings of animal models must be evaluated in terms of their inherent limitations. Most animal studies involve quadrupeds; thus, the loading imposed on the spinal instrumentation may not represent the loading that it would experience in patients. For example, in the study mentioned earlier, McAfee et al. used a complete corpectomy model, with the device spanning the vertebrectomy space. In patients, one would expect a degenerated disc or interbody bone graft between the vertebral bodies. Hence, in the experimental model, the device assumed 100% of the load in contrast to the load-sharing capabilities for which it was designed.

The greatest value of animal studies is to provide bioengineers and clinicians with data as to how the osseous and soft tissues adapt to the altered loading environment produced by instrumentation. They also demonstrate the impact of normal and altered biology on the healing process.

The biomechanical evaluation of spinal fusion and stability has produced a large knowledge base that has allowed for the design, development, and implementation of progressively more sophisticated devices. The preceding methods are used to demonstrate the safety and potential effectiveness of instrumentation. Of course, the ultimate measure of efficacy of any system is based on well-designed and selected studies.

**AUTHORS’ PERSPECTIVE**

The human disc, facets, and the ligaments of a spinal segment work in unison to transmit loads and permit motion. If the degenerative process, trauma, or any other factor affects an anatomic component, changes in loading and motion patterns result. Modern imaging techniques and clinical observations have adequately delineated morphologic changes in certain spinal structures that may precede degeneration of the spine. A surgeon combines this information with his or her experience to assess instability and the need for surgery, especially when conservative treatment options fail to produce satisfactory results.

The choice of technique, whether anterior, posterior, or interbody, and fixation system must be approached from a biomechanical perspective. The biomechanical data available can make the choice a more informed one. On a short-term basis, rigid fixation devices (both anterior and posterior) are capable of imparting stability to an injured or unstable segment. The degree of stability imparted, at least in the physiologic range of motion, does not vary significantly with the screw size, implant shape, or other variables.

The rigidity of the construct and the ability of a spinal fixation device to share a load with the maturing fusion mass are essential for fusion to occur. If the load transferred through the fusion mass is increased without sacrificing the rigidity of the construct, a more favorable environment for fusion may be created. Finally, although a host of experimental methods have enabled researchers to evaluate initial device performance and failure characteristics, the true measure of a device’s effectiveness can be assessed only through properly designed clinical outcome studies.

CHAPTER 138

SURGICAL APPROACHES TO THE SPINE

Robert G. Watkins

As late as 1980, spinal surgeons, and therefore spinal patients, were severely limited in the options available to them for surgical treatment. The source of this limitation was a combination of technology and the experience in surgical approaches. Very few spinal surgeons had the ability to approach every aspect of the spine with the optimal exposure. Spinal access surgeons were few and far between. The microscopic and endoscopic approaches that protect normal tissue and speed recovery were scarcely available to unavailable. The evolution of spinal surgery now allows the surgeon to approach their pathology so as to optimize the resection of a pathologic lesion and reconstruct the spine to optimal biomechanical advantage. Perfecting the approach is the first step to perfecting the surgery and a major step in protecting the patient.

THE CERVICAL AND THORACIC SPINE

POSTERIOR APPROACH TO C1–C2

- For the posterior cervical exposure of any level, position the patient's head in the self-retaining neurosurgical head fixation device that is attached to the surgical table. Attach the drapes to the patient's neck with stay sutures. Neck flexion will increase exposure, but flexion is limited by the type of pathologic process present, usually to a neutral, slightly flexed position. In the presence of spinal instability, confirm the position of the spine with radiographs.

- Incise the skin and subcutaneous tissue in the midline to the fascia, and obtain hemostasis with rapid application of hemostats and electrocautery. Insert self-retaining retractors.

- Deepen the incision with the cautery knife, staying within the thin white median raphe; avoid cutting muscle tissue. The medial raphe of the cervical spine is a delicate structure that does not follow a straight path. Open the median raphe to the spinous processes of C-2 and C-3, the occiput, or any level needed. In children, expose no spinal levels unnecessarily to avoid spontaneous fusion at adjacent levels, including the occiput.

- With a #15 blade or cutting cautery, expose the bulbous bifid tips of the spinous processes. The ligamentous attachments to C-2 are very prominent. The large ligamentous attachments at C-2 may be dissected with great care and without damage to underlying structures. Insert self-retaining retractors.

- Often the C-1 ring is very thin, and direct pressure can fracture it or cause the instrument to slip off the ring and penetrate the atlantooccipital membrane. With a #15 blade or cutting cautery, expose the bulbous bifid tips of the spinous processes. The ligamentous attachments to C-2 are very prominent. The large ligamentous attachments at C-2 may be dissected with great care and without damage to underlying structures. Insert self-retaining retractors. Elevate on this ring can be very dangerous if there is subluxation with constriction of the posterior dura under this ring. The dura may be vulnerable on both the superior and inferior edges of the ring of C-1.

- At the level of C-1, dissect laterally only approximately 1.5 cm. The second cervical ganglion is an important landmark on the ring of C-1 laterally; it lies approximately 1.5 cm laterally on the lamina of C-1 in the area of the groove for the vertebral artery. Carefully identify the most medial aspect of the groove for the vertebral artery and vein on the superior border of the C-1 ring. The bluish color of the vein is visualized first. By seeing the initial ridge or the vein, damage to the vertebral artery and vein can be avoided. There is seldom any indication for dissection lateral to the groove of the vertebral artery on C-1. The vertebral artery and vein are vulnerable in the groove; in addition, as the artery passes from the foramen transversarium of C-2 to that of C-1, it is in close proximity laterally and posteriorly to the joint (29) (Fig. 138.1 and Fig. 138.2).

- Elevated from medial to lateral for a width of approximately 1 inch (2.5 cm) at each level. At levels below C-2, identify the medial edge of the facet joint at the base of the lamina and pack each level as it is exposed. When necessary, expose the occiput with elevators. Insert the self-retaining retractors to expose the base of the skull and the dorsal spine of C-2. The area in between will contain the ring of C-1. This is often very deep compared with the spinous process of C-2.

- Maintaining firm lateral retraction of the wound, identify the posterior tubercle of C-1 longitudinally in the midline by probing with a sharp Cobb elevator. Begin the subperiosteal dissection to expose the bone.

- Often the C-1 ring is very thin, and direct pressure can fracture it or cause the instrument to slip off the ring and penetrate the atlantooccipital membrane. Elevation on this ring can be very dangerous if there is subluxation with constriction of the posterior dura under this ring. The dura may be vulnerable on both the superior and inferior edges of the ring of C-1.

- The course of the vertebral artery is from the foramen transversarium of C-1 posteriorly in the region of the C1–C2 articulation through the transversarium of C-1, then posteromedially to the posterior rim of C-1.
The vertebral artery enters the foramen transversarium at the sixth vertebra and progresses cephalad. It exits through the foramen transversarium of C-1 and progresses posteriorly as well as medially in the groove of the superior border of C-1 toward the midline, then turns cephalad along the spinal cord to enter the foramen magnum. The vertebral artery can be damaged by penetrating the atlanto-occipital membrane off the superior border of the ring of C-1 more lateral than the usually safe 1.5 cm from the midline.

Following exposure of the ring of C-1 and exposure to bone of the posterior occiput, different operative procedures require exposure of the dura under the edge of the foramen magnum (17,25,26). Never attempt to decompress the posterior fossa under the edge of the foramen magnum without sufficient visualization of the area cephalad to the foramen. This is best accomplished by placing two burr holes just off the midline of each side of the skull (Fig. 138.3). The caudal extent of the holes is usually determined by the angle of the drill on the skull as limited by the patient’s shoulders.

In the posterior approach to the foramen magnum, first place burr holes in the occiput above the foramen magnum. Two parasagittal holes allow removal of bone from the dura with a Harrison-type rongeur. Careful dissection medially from the burr holes provides protection from the often significant fragile venous sinus, and dissection caudally approaches the foramen magnum. After removal of the occiput including the bony rim of the foramen magnum, which is a sharp-tipped structure projecting directly anterior in the transverse plane, the fibrous attachment of the inner periosteum of the skull to the dura at the rim of the foramen magnum is encountered. When a transverse venous sinus in this area is torn, bleeding can be significant. Attachment to the dura in this area produces a dural leak unless the area is carefully dissected.

Penetrate to the inner periosteum and the bone edge with a small dissector. Expand the hole caudally to the foramen with rongeurs. The edge itself curves under and projects anteriorly. The periosteum of the skull at this point is often conjoined with the dura of the spinal cord. There is a median venous sinus in the midline, and the fascial attachment of the periosteum of the skull to the dura often contains a transverse sinus as well.

Passing instruments under the edge of the foramen can produce dangerous bleeding in the posterior fossa with no means of control. Therefore, resect the bone down to this edge from above.

For a more lateral approach to the C1–C2 facet joint, the vertebral artery between C-1 and C-2 must be identified. In rotatory dislocations of C1–C2, the artery is stretched tightly across the joint on the side that C-1 is anterior to C-2, and it is easily damaged (29).

For nerve root exposure below C-2, identify the junction of the lamina and the inferior facet. Then identify the junction of the interlaminar area and the facet joint. Expanding these areas with a burr or a micro-Kerrison rongeur allows entry into the intervertebral foramen and exposure of the nerve root.

**TRANSORAL APPROACH TO C1–C2**

For preoperative preparation, take oral and nasal cultures of the patient in case problems develop later (1). Use standard prophylactic antibiotics because no special antibiotic coverage for normal oral flora is needed. I do not use preoperative antiseptic gargles or tetracycline (7).

Always perform a tracheostomy, using a short-cuffed tube.

- Position the patient supine with the head slightly flexed on occipital pads, or put the head into a halo. A more upright position can be used with certain precautions.
- The Boyle-Davis or Mcvor ear, nose, and throat (ENT) retractor allows depression of the tongue and self-retaining retraction of the mouth. The lips and teeth should be adequately padded.
- Incise the soft palate with a curvilinear incision around the uvula, and retract the cut edges with stay sutures to the lateral walls of the oropharynx or to an especially bent, blunt-tipped Gelpi retractor (7,14). Prep the oropharynx with povidone-iodine (Betadine) solution and reculture it.
- Enhanced hemostasis by injecting the posterior pharyngeal tissue with a solution of 5% lidocaine and 1:500,000 epinephrine.
- After palpation and radiographic confirmation of the ring of C-1, make a vertical incision from approximately 1 cm cephalad to the tip of the odontoid to 2 cm distal to the anterior tubercle of C-1. Incise the four layers (posterior pharyngeal mucosa, superior constrictor muscle of the pharynx, the prevertebral fascia, and the anterior longitudinal ligaments) directly to the bone.
- Bluntly dissect the soft tissue off the body of C-2 below the odontoid and off the anterior tubercle of C-1.
- Caution: The longus colli muscle inserts on the anterior tubercle of C-1, and sharp dissection may be needed to remove it. Venous bleeding may arise from the recesses just lateral to the base of the odontoid.
- When necessary, the lateral masses of C1–C2 can be exposed by bluntly dissecting the bone both transversely and vertically.
- Caution: Avoid plunging lateral to the facet joints. To avoid damage to the internal carotid, do not pass a stay suture too deeply into the lateral pharyngeal wall.
- Remember, this is a deep wound, requiring long instruments with fine tips. Most operations done with this exposure require use of the microscope for lighting and magnification.
- After the bony work is completed and good hemostasis is obtained, close the posterior pharynx in a single layer with interrupted absorbable sutures.

**ANTEROLATERAL APPROACHES TO C-1, C-2, AND C-3**

- Position the patient supine with the appropriate support for the cervical spine mentioned earlier. For two levels of pathology, it is a transverse incision, one fingerbreadth medial to the medial border of the sternocleidomastoid. Open layers in a fashion similar to that used with the standard cervical approaches.
- For higher anterior approaches to C-1, C-2, and C-3, identify the superior thyroid artery and vein. The superior thyroid artery arises from the external carotid artery at approximately the level of the hyoid bone. It crosses through the carotid triangle, arches deep to the strap muscles, and enters the lateral superior aspect of the thyroid gland. Retract the superior thyroid artery and vein inferiorly.
- Identify and retract the hypoglossal nerve. The hypoglossal nerve is found passing from lateral to medial superficial to the external carotid, lingual, and facial arteries (Fig. 138.4). It exits the skull in close proximity to the vagus nerve and courses beneath the internal carotid artery and internal jugular vein, becoming superficial at the angle of the mandible. After the usual point of identification of the hypoglossal nerve over the arteries, it passes deep to the tendon of the digastic muscle and stylohyoid muscle for distribution to the muscles of the tongue. Retract the hypoglossal nerve cephalad; usually, the superior thyroid artery and vein are retracted caudad.

---

**Figure 138.2.** The anterior view without vertebral bodies emphasizes the formation of the anterior spinal artery. There are numerous variations in this formation, ranging from a unilateral vertebral artery contribution to no contribution.

**Figure 138.3.** Posterior approach to the foramen magnum.

**Figure 138.4.** Dissected anatomy of the carotid triangle and area just below emphasizes the importance of identification of the hypoglossal nerve before ligation of the arterial structures in this area. The most common approach is cephalad to the superior thyroid artery and caudad to the digastic muscle. SCM,
ANTEROMEDIAL APPROACH TO THE MIDCERVICAL SPINE

- Be certain of the identification of the hypoglossal nerve before ligating any structure. It is a superficial structure, first coursing vertically and parallel to the carotid sheath, then horizontally, crossing medi ally over the carotid and its branches.
- Identify the lingual artery, which arises from the external carotid. From the level of the hyoid, it courses under the diastatic and stylohyoid muscles in its ascent to the oral pharynx.
- Identify and ligate the facial artery. The facial artery next leaves the external carotid artery, coursing under the ramus to the mandible within the carotid triangle. It passes deep into the diastatic muscle and enters the face at the anterior edge of the mastoid after crossing on the submandibular gland.
- Identify the digastic muscle. This muscle is easily retracted cephalad with the hypoglossal nerve. When necessary, divide the stylomastoid band running from the stylohyoid process to the posterior pharynx.
- Identifying the anterior scalene muscle is a critical step in the exposure of the midcervical spine. Both the cephalic and ceph alad processes, and superior to the rachial line. The interval between the two laminae of the external investing fascia is called the suprasternal space, or the space of Burns. This space, which contains the anterior jugular veins and sternal head of the sternocleidomastoid, is referred to as the cul-de-sac of Bruger. Communication between the anterior and external jugular veins is channeled through this inner laminar area.
- The middle cervical fascia attaches to the carotid sheath and joins the external investing fascia at the posterior border of the sternocleidomastoid muscle. Inferiorly, the middle cervical fascia attaches to the posterior surface of the sternum, as do the muscles that they cover. It is the middle cervical fascia that attains to the clavicle and forms the loop for the inferior belly of the omohyoid muscle.

The external investing fascia forms the anterior and posterior sheaths of the sternocleidomastoid muscle and the fascial covering of the visceral structures of the neck (10). This investing layer of cervical fascia is attached inferiorly to the clavicles, clavicle, and manubrium of the sternum in an outer and inner layer superiority to the hyoid bone, posteriorly to the mandible and mastoid processes, and superior to the rachial line. The interval between the two laminae of the external investing fascia is called the suprasternal space, or the space of Burns. This space, which contains the anterior jugular veins and sternal head of the sternocleidomastoid, is referred to as the cul-de-sac of Bruger. Communication between the anterior and external jugular veins is channeled through this inner laminar area.

The middle cervical fascia attaches to the carotid sheath and joins the external investing fascia at the posterior border of the sternocleidomastoid muscle. Inferiorly, the middle cervical fascia attaches to the posterior surface of the sternum, as do the muscles that they cover. It is the middle cervical fascia that attaches to the clavicle and forms the loop for the inferior belly of the omohyoid muscle.

The prevertebral fascia is continuous with the endothoracic fascia caudally, and laterally it covers the levator scapulae and splenius muscles. It extends posteriorly to attach to the spinous processes of the vertebrae. In the neck throughout the spinal column, it covers the longus colli and capitus muscles and is secured to the tips of the transverse processes.

The origin of the anterior scalene muscle rises from the anterior tubercles of the transverse processes of C-3, C-4, C-5, and C-6. It inserts into the scalene tubercle on the inner border of the first rib and into the ridge on the cranial surface of the rib ventral to the subclavian groove. The scalenus medius originates from the posterior tubercle of the transverse processes of the last six cervical vertebrae and inserts into the first rib.

The scalenus medius is a muscular reinforcement of Sibson's fascia. These fascial connections and the scalenus minimus connect the transverse processes of the seventh cervical vertebra to the first rib. Sibson's fascia, as a portion of the prevertebral fascia, becomes continuous with the endothoracic fascia on the inner surface of the first rib. Extending medially between the anterior scalene muscle and the spine is the all-important retropharyngeal fascial cleft. This is the space beneath the visceral structures, superficial to the prevertebral fascia; it is in this space that retraction and work on the anterior portion of the spine takes place.

ANTEROMEDIAL APPROACH TO THE MIDCERVICAL SPINE

- Position Gardner-Wells tongs or headhalter traction for cervical traction. Position the head in slight extension and rotation to the right. Contour a small, curved sand bag under the neck to support the spine. Drape off the entire neck with adhesive towel drapes. Select the level of the skin incision. Superficial landmarks are used to determine the appropriate placement of the skin incision over the appropriate level of the spine. For approaches to C-1, C-2, and C-3, start the incision midline extended to the lateral border of the carotid sheath, one fingerbreadth below the angle of the mandible. For approaches to C-2–C-3 start the incision at the midline and extend it to the lateral border of the sternocleidomastoid at the level of the cephalad margin of the thyroid cartilage. For C-4–C-5, start the incision at the midline extended to the medial border of the sternocleidomastoid at the level half way between the cricoid cartilage and the superior border of the thyroid cartilage. For C-5–C-6, start the incision at the midline on the cephalad margin of the cricoid cartilage and extend it to the medial border of the sternocleidomastoid. For C-6–C-7, start the incision at the midline on the caudal margin of the cricoid cartilage and extend it to the medial border of the sternocleidomastoid. For C-7–T-1, start the incision at the midline; extend it just lateral of the medial border of the sternocleidomastoid, halfway between the cricoid cartilage and the clavicle. We prefer the midline starting point, because retraction of the medial muscular visceral column is the strongest structure requiring retraction. Having the skin open to the midline eases that retraction. The self-retracting retractor is placed in the midline. Having the skin open to the midline aids in that retraction.

- After making a transverse skin incision at the appropriate level (Fig. 138.6), dissect through the subcutaneous tissue to the platysma muscle. Elevate the platysma muscle with Adson forceps, and open it carefully, in the line of the fibers, when possible. Beware of damage to veins and the sternocleidomastoid muscle (22). Insert a spring retractor.

The external investing fascia forms the anterior and posterior sheaths of the sternocleidomastoid muscle and the fascial covering of the visceral structures of the neck (10). This investing layer of cervical fascia is attached inferiorly to the archon, clavicle, and manubrium of the sternum in an outer and inner layer superiority to the hyoid bone, posteriorly to the mandible and mastoid processes, and superior to the rachial line. The interval between the two laminae of the external investing fascia is called the suprasternal space, or the space of Burns. This space, which contains the anterior jugular veins and sternal head of the sternocleidomastoid, is referred to as the cul-de-sac of Bruger. Communication between the anterior and external jugular veins is channeled through this inner laminar area.

The middle cervical fascia attaches to the carotid sheath and joins the external investing fascia at the posterior border of the sternocleidomastoid muscle. Inferiorly, the middle cervical fascia attaches to the posterior surface of the sternum, as do the muscles that they cover. It is the middle cervical fascia that attaches to the clavicle and forms the loop for the inferior belly of the omohyoid muscle.

The prevertebral fascia is continuous with the endothoracic fascia caudally, and laterally it covers the levator scapulae and splenius muscles. It extends posteriorly to attach to the spinous processes of the vertebrae. In the neck throughout the spinal column, it covers the longus colli and capitus muscles and is secured to the tips of the transverse processes.

The origin of the anterior scalene muscle rises from the anterior tubercles of the transverse processes of C-3, C-4, C-5, and C-6. It inserts into the scalene tubercle on the inner border of the first rib and into the ridge on the cranial surface of the rib ventral to the subclavian groove. The scalenus medius originates from the posterior tubercle of the transverse processes of the last six cervical vertebrae and inserts into the first rib.

The scalenus medius is a muscular reinforcement of Sibson's fascia. These fascial connections and the scalenus minimus connect the transverse processes of the seventh cervical vertebra to the first rib. Sibson's fascia, as a portion of the prevertebral fascia, becomes continuous with the endothoracic fascia on the inner surface of the first rib. Extending medially between the anterior scalene muscle and the spine is the all-important retropharyngeal fascial cleft. This is the space beneath the visceral structures, superficial to the prevertebral fascia. This is in this space that retraction and work on the anterior portion of the spine takes place.
**Figure 138.7.** The key to the dissection at this point is to identify the medial border of the sternocleidomastoid muscle. With lateral retraction of the sternocleidomastoid, the interval between this muscle and the medial strap muscles is delineated.

- Retract the sternocleidomastoid laterally and the strap musculature medially with angled retractors. Identify the middle cervical fascia. The omohyoid muscle crosses from proximal medial to lateral distal through the middle cervical fascia at C6–C7. Retract the omohyoid; when necessary, divide it and later repair it in its midline position.
- After retracting the sternocleidomastoid muscle laterally and the strap musculature medially, identify the arteriovenous structures of the middle cervical fascial layer (Fig. 138.8). Palpate the carotid pulse. Open the midline cervical fascia medial to the carotid artery. Ligate and tie the medial thyroid vein. Retract cephalad the superior thyroid artery and retract caudad the inferior thyroid artery to expose the midcervical spine.

**Figure 138.8.** Arteriovenous structures of the middle cervical fascial layer.

- Spread the middle cervical fascia just medial to the carotid sheath (23), with finger dissection spreading vertically and horizontally (3). Identify the inconstant middle thyroid vein crossing at approximately C-5, and ligate and divide it when needed. Identify the spine with finger palpation of the anterior surface of the vertebral body. Insert a blunt, nonlipped Cloward hand-held retractor into the wound directly down to the spine. Hold the retractor on the right longus colli. Beware of entering the tracheoesophageal groove (and thereby damaging the recurrent laryngeal nerve with the retractor tip) (19).
- Distally retract the inferior thyroid artery and vein at the C6–C7 level, and proximally retract the superior thyroid artery and vein with the superior laryngeal nerve at C3–C4.
- Do not mistake the transverse process for the anterior surface of the vertebral body because an incision deep in this area will damage the longus colli, the sympathetic chain, and possibly the vertebral artery. An incision into the longus colli produces bleeding.
- Palpate a disc in the midline of the spine and open the prevertebral fascia with a small dissector longitudinally until the disc can be identified. If the finger dissects directly to the spine and the retractor is then inserted, the esophagus cannot be seen. The empty esophagus is only a soft, flat ribbon-like structure simulating the mucosal surface of the anterior portion of the spine. Always use either an esophageal stethoscope or a nasotracheal tube to identify the esophagus.
- Insert a needle into a disc for lateral radiographic confirmation of the level.
- Retract the esophagus, trachea, and anterior strap muscles medially and the carotid sheath and sternocleidomastoid muscle laterally.
- Incise the prevertebral tissue in the midline on the disc. Use a bipolar coagulator along the medial edge of the longus colli as needed. Using sharp periosteal elevators, fashion a flap of muscle under which the retractor can be inserted laterally from the midline. Insert the clawed blades of the Cloward deep self-retaining retractor under the longus colli on both sides of the spine. To expose the desired disc, use the blunt-tipped Cloward retractor vertically (6).
- Insert the clawed retractor first. Hold it down on the spine while inserting the near retractor. The Cloward curved periosteal elevator can lift up the flap for insertion of the blade retractor.
- After hemostasis has been achieved, close the deep wound by removing the retractors. Use subcuticular skin closure, and always use a closed suction wound drainage system.

**SUPRACLAVICULAR APPROACH**

- Place the patient in the supine position with the neck slightly hyperextended and rotated away from the side of the approach. Use an inflatable cervical pillow for support; a small roll under the shoulder often helps to extend the neck.
- Caution: Location of the thoracic duct and recurrent laryngeal nerve becomes even more important at this level. Approaches from the left for C6–T2 are directly in the vicinity of the thoracic duct. Identify the thoracic duct when possible and protect it. A large fatty meal the day before surgery will help. If the thoracic duct is inadvertently divided, double ligate both ends well. The approach to the right definitely requires identification and protection of the recurrent laryngeal nerve. I recommend the left supraventricular approach to avoid risk to the recurrent laryngeal nerve.
- Maintain an approximate incision approximately 2 inches above the clavicle from the midline to the posterior border of the sternocleidomastoid muscle. After the skin and subcutaneous tissue are divided and small skin self-retaining retractors are placed, incise the platysma muscle in the line of the incision. As in the higher approaches, identification of the medial border of the sternocleidomastoid muscle is imperative.
- In addition, identify and define the anterior and posterior borders of the sternocleidomastoid muscle. The external jugular vein, although somewhat variable, is usually directly in the operative field, and the anterior jugular vein is positioned more medially. Divide it, if necessary.
- Incise the external investing fascia. Pass a probe or finger laterally from the medial border of the sternocleidomastoid to clear off the venous structures underneat the clavicular head of the sternocleidomastoid.
- Divide the sternocleidomastoid laterally to medially 1 inch from its insertion, watching for the internal jugular vein (12). If required for visualization, remove the sternal head of the sternocleidomastoid muscle in the same fashion. Eventual reattachment depends on suturing the fascial covering of the muscle.
- Retract the divided sternocleidomastoid in a cephalad-caudal direction with self-retaining blunt retractors. The floor of the incision, at this point, consists of the middle cervical fascia, which contains the omohyoid and the sternohyoid muscles.
- Enter the middle cervical fascia lateral to the carotid sheath. Bluntly dissect to the surface of the anterior scalene muscle. The superficial surfaces of the anterior scalene are composed of the outer layer of prevertebral fascia, which is the third and deepest of the fascial layers dealt with in this approach. Lying on the surface of the anterior scalene muscle is the phrenic nerve. The phrenic nerve crosses from lateral to medial, and cephalad to caudad. Retract the phrenic nerve medially after freeing it from the surface of the anterior scalene muscle. Identify the large internal jugular vein medially and feel for the carotid pulse. Although retraction of the carotid sheath is possible laterally, attempt to retract the internal jugular vein and carotid sheath medially. Retract the phrenic nerve to obtain good visualization of the anterior scalene, which is between the phrenic nerve and the middle scalene. The brachial plexus and suprascapular nerves are more superficial at the lateral border of the anterior scalene.
- Delineate the medial and lateral borders of the anterior scalene muscle. The fascia on the deep surface of the anterior scalene is Sibson's fascia, a continuation of the prevertebral fascia that encloses this muscle. The apex of the paretal pleura and lung form the undersurface of Sibson's fascia.
- Retract the anterior scalene laterally. Now carry out blunt dissection medially under the retracted carotid sheath. Stay on the prevertebral fascia of the spine.
- If more exposure is needed, carefully approach under the anterior scalene without violating the major portions of Sibson's fascia, and divide the anterior scalene muscle. The scalene can be retracted cephalad to caudad with self-retaining blunt retractors. Sibson's fascia now makes up the floor of the wound; the large internal jugular vein and the carotid sheath are located medially; the apex of the lung is beneath Sibson's fascia in the floor of the wound; and laterally, the brachial plexus courses superficial to the scaleneus medius. The proximal portion of the anterior scaleneus muscle may be dissected from the anterior tubercle of the transverse processes to allow greater exposure of the spine or brachial plexus (22).
- Incise Sibson's fascia at the transverse processes and bluntly retract it inferiorly. This retracts the pleura of the lung, which is usually at the T-1 level. Mobilize the recurrent laryngeal nerve medially with the carotid sheath and medial visceral column. Expose the spine by opening the fascia in the midline over the body. The transverse processes and rib heads can be exposed (15).
- Dissect to the second and third rib heads. This provides a rather lateral exposure of the spine. From the rib heads, dissect medially to enter the retropharyngeal fascial cleft on the anterior surface of the spine without having to dissect the longus colli muscle. Identify the vertebral artery entering the spine at C6–C7.
subclavian vein courses on the floor of the wound.

- If the approach is done from the left, the junction of the internal jugular veins and the subclavian veins will contain the thoracic duct. Identify the thoracic duct. In case of damage, double ligate it proximally and distally. Chylothorax can be prevented with proper ligation. Often, a more judicious approach involves blunt dissection, progressing cephalad to caudal, as has been described for the transverse processes of C-5, C-6, and C-7, to the rib head of the first rib down on the spine. This will sweep most of these structures cephalad to caudal. The danger, of course, lies in cutting restraining structures that cross the field. The sympathetic chain (stellate ganglion at C-7) lies on the rib heads in a lateral position. Avoid damage by dissecting more medially.

THIRD RIB RESECTION IN THE TRANSTHORACIC APPROACH

Third rib resection is used for the transthoracic approach to the T1–T4 area. Resection of the third rib allows greater spreading of the intercostal area than does second rib resection (13). The cephalad extension of the exposure is enhanced with kyphosis deformity of the cervicothoracic junction area. The second rib can be removed if the operative exposure is inadequate.

- Place the patient in the lateral decubitus position, with the left side up. Prep and drape the entire left upper extremity in a sterile manner (Fig. 138.9).

Figure 138.9. Skin incision for third rib resection for the transthoracic approach.

- Incise the skin and subcutaneous tissue from the lateral paraspinal area at T-2, along the medial caudal border of the scapula, under the axilla to the costal cartilage of the third rib.

- Carefully divide each subsequent muscle layer down to the level of the rib, sectioning portions of the trapezius, latissimus dorsi, rhomboid major, and serratus posterior as needed. Careful dissection with electrocautery and meticulous cauterization of each muscle bleeding point allows exposure to the outer periosteum of the third rib with a minimal amount of bleeding. As the muscle layers are divided, retract the scapula cephalad and medially to tense the muscle tissue for easier cutting. Palpate the chest wall cephalad for identification of the third rib. Remember that the first rib is situated inside the second; this is important for reaching the correct rib level (Fig. 138.10).

Figure 138.10. Elevation of the scapula aids in the division of the muscles attached to the scapula and allows visualization of the third rib.

- Dissect the external periosteum off the third rib with periosteal elevators. Excise the third rib from the angle of the rib to the costal cartilage. Open the rib bed as in the standard thoracotomy approach (Fig. 138.11). The rib bed consists of periosteum, endothoracic fascia, and parietal pleura. Incise the parietal pleura, carefully avoiding damage to the underlying lung. Pick up the inner periosteum of the rib with Adson forceps and open the rib bed with scissors tips or fine dissection with a knife blade. To avoid lung and pleural adhesions just under the rib, complete the opening of the rib bed with semiclosed scissors, using a finger to clear lung from the undersurface.

Figure 138.11. Excise the third rib from the angle of the rib to the costal cartilage.

- Use the Feochetti rib spreader to open the intercostal area. Deflate or retract the lung with a spatula-type retractor (Fig. 138.12).

Figure 138.12. With the rib bed open, place the Feochetti rib-separating retractor and retract the lung with a spatula lung retractor.

- Identify the aorta, spine, ribs, parietal pleura, and veins under the parietal pleura in the wound. The highest intercostal vein is usually seen.

- Use an Adson forceps and Metzenbaum scissors to open the parietal pleura delicately over the costovertebral articulations.

- Identify the prominent soft or white tissue of the intervertebral disc. This is a relatively avascular, safer plane for dissection than the surface of the vertebral body. Make an intraoperative radiograph to verify the level.

- Dissect each intercostal vessel, lying and ligating it over the vertebral body. Bluntly dissect the soft tissue from the vertebral body (Fig. 138.13).
When the pathology dictates a direct anterior approach to the vertebral column (e.g., kyphotic tuberculous abscess), choose the rib directly horizontal to the vertebral level at the midaxillary line in an anteroposterior chest radiograph. The rib removed must be cephalad to the lesion to give adequate proximal exposure of the lesion (13).

When direct access to the spinal canal is needed at one disc (e.g., ninth rib to the T8–T9 disc), use a left approach because it is much easier to deal with the aorta and the segmental vessels from the left side. For patients with a large abscess in the right chest or in other circumstances that dictate a right thoracic approach, be prepared to mobilize the vena cava and associated veins from that side.

Place the patient on the bean bag. Use a double-branched endotracheal tube into the right and left mainstem bronchi to allow selective collapse of the left lung. Center the midthorax of the patient over the break in the table. Pad the dependent axilla, and pad and protect the left arm. Stabilize the pelvis with a strap to the table. Place a pillow between the legs, and pad all the bony prominences. Flex the table to allow better exposure.

Open the skin and subcutaneous tissue from the lateral border of the paraspinal musculature to the sterno-costal junction over the rib to be resected. Inject the incision with 1,500,000 epinephrine. Place the thoracotomy incision slightly tangential to the rib to be resected, allowing easier resection of more than one rib if necessary.

After inserting the self-retaining retractors, extend the wound with the electrocautery down through the muscle layers to the thorax. When necessary for full exposure, the latissimus dorsi, trapezius, and rhomboid major and minor muscles can be sectioned.

After the chest wall is exposed, count the ribs from the twelfth up to the appropriate rib or from the first rib downward. The first rib appears to be inside the second when one is palpating from this angle, and it is often difficult to find. Each rib articulates with the superior portion of the body in the area of the disc space of the level above. Therefore, the twelfth rib inserts closer to the T11–T12 intervertebral disc space. Confirm identification of the rib with a radiograph.

Expose the outer periosteum of the rib with the electrocautery and cut directly to the bone through the periosteum from the angle of the rib to the costal cartilage. Elevate the periosteum off the outer rib surface. Use the curved-tip rib elevator to strip the superior and inferior borders of the rib, maintaining an intact elevated periosteum. Elevate the inner periosteum of the undersurface of the rib with the Doyen elevator. Avoid damaging the intercostal vessels that course on the inferior surface of the rib. Elevate the periosteum of the rib by cutting with the elevator directly on bone. Avoid plunges that might inadvertently enter the pleura.

With the intact periosteum freed from the rib, cut the rib with the rib cutter as far posteriorly as necessary between the costotransverse joint and the angle of the rib and anteriorly at the costal junction. Remove the rib and save it for bone graft. Lightly wax the bone on the end of the rib after rasping to make sure there are no ragged edges. Tie a sponge on the tip of the stump to protect the surgeon during the procedure.

Pick up the inner periosteum of the rib bed with Adson forceps and open the rib bed with scissors. Avoid lung and pleural adhesions. Complete the opening of the rib bed with a semiclosed scissors after using a finger to clear lung from the undersurface. When pleural adhesions exist, first attempt to dissect the adhesions bluntly with the finger or sponge stick. If necessary, sharply dissect dense adhesions and ligate vascular structures.

Retract the lung medially with a spatula lung retractor or deflate it. Retraction of the lung should be removed at least every 20 minutes to allow adequate expansion of the lung and to prevent postoperative atelectasis. Insert the Feochetti separator in the rib resection defect, with moist lap sponges over the edges. Expand the Feochetti separator to allow adequate visualization inside the thoracic cavity. Flexion of the table may be of benefit.

The anatomy of the spine at this point is obscured by the reflection of the parietal pleura as it covers the soft-tissue structures over the spinal column. Elevate the parietal pleura with Adson forceps and open it with Metzenbaum scissors. Extend the opening of the parietal pleura cephalad and caudad on the spine by cutting over a bean dissected under the pleura. The presence of a large paravertebral abscess at this point means only that the abscess should be exposed just as the spinal column and the abscess is processed, cu an outer wall longitudinally and approach the spine through the abscess.

The disc is the more prominent, softer, white structure of the spine. The discs are relatively avascular and a much safer area for dissection. An intercostal vein and artery cross the midportion of each vertebral body.

Bluntly dissect the edges of the parietal pleura off the spine with a Kittner dissector or sponge. Elevate the pleura on the discs and lift it off the vessels on the vertebral body. Dissection begun over the disc is less likely to cause bleeding. Make a radiograph at this point to verify the level. After the parietal pleura is opened, it may be sutured back on itself laterally with two stay sutures.

Separate, sever, and ligate each of the intercostal vessels over the vertebral body. If a large paravertebral abscess is present, the arteries enter the abscess. Take care to avoid clamping segmental arteries too close to the aorta so as to lose the tie or too close to the intervertebral foramen. Tie arteries and veins separately or together, depending on the vessel and then the lateral exposed vessels; use vascular clamps in a similar fashion.

Caution: Take care to dissect adequately under the vessels. A common mistake is to have both ligature sutures in the same place under the vessel and not have adequate room for cutting between them. Pass a right-angled clamp under the vessels, and use a braided 2-0 suture in a free tie to tie off first the medial and then the lateral exposed vessels; use vascular clamps in a similar fashion.

Caution: Do not dissect into the intervertebral foramen.

Bluntly expose the outer surface of the spine after division of the segmental vessels. When bone and disc exposure is needed, cut with the cautery directly to bone. Use the periosteal elevator to dissect the annulus off the disc and the periosteum off the bone medially and laterally, exposing the entire disc and vertebral column. The tendency is not to dissect the soft tissue laterally enough off the spine. The rib head articulates with the cephalad half of its appropriate vertebral body and the disc space above. Access to the posterior disc and spinal column can be gained by resecting the rib head (Fig. 138.14). Removal of the head of the rib and its articulation allows excellent exposure of the posterolateral aspect of the intervertebral disc. After the rib head and disc are removed, identify the intercostal nerve, dural sac, posterior vertebral body wall, and spinal canal. The costal vertebral articulation is a major stabilizing structure in the thoracic spine.

Figure 138.14. The rib articulates with the cephalad half of its appropriate numbered vertebral body and with the disc space above. Therefore, the tenth rib articulates at T9–T10.
Visualize the lung fully expanded in all areas before closure. Close the parietal pleura over the spine whenever possible. Place the chest tube through a separate aperture, preferably in the ninth intercostal space. Protect the lung during closure. Close the chest with the rib approximator. Close the rib bed with interrupted permanent braided Dacron sutures. The chest tube connects to the water seal. With the lung re-expanded, the chest tube can usually be removed within 48 to 72 hours, depending on drainage and expansion of the lung.

THE THORACOLUMBAR JUNCTION

The rules for resecting the best rib for exposure of the thoracolumbar junction are much the same as in the rest of the thoracic spine. Hodgson and Rau (13,14) recommend a ninth rib resection for T10–L1. Dwyer et al. (6) recommend a tenth rib resection with the standard thoracolumbar approach for the T10–L1 area. For exposure of the T12–L1 area, Perry (15) recommends a tenth rib resection. Ideally, choosing the rib in the midaxillary line opposite the lesion or the apex of a curve allows adequate proximal exposure for working “down” or caudal on the lesion.

Transthoracic resection of the ninth rib is usually best for maximum exposure of T11–T12. A tenth rib thoracoabdominal approach is preferred for exposure of the T12–L1 area. Both techniques involve detaching the diaphragm at its circumference. A twelfth rib approach is used in cases in which less exposure is needed or when it is imperative that the diaphragm not be taken down. A twelfth rib extrapleural retroperitoneal approach is recommended for exposure of L1–L2.

The approach through the eleventh rib, a more demanding approach with less expansive exposure, is the highest practical, extrapleural, retroperitoneal anterior approach for the exposure of the T10–L2 area. It is ideally used in severely ill patients in whom avoiding opening the pleural cavity and cutting the diaphragm is an advantage. Another alternative for limited extrapleural exposure with low morbidity is the posterior costotransversectomy approach. The vertebral body and spinal canal can be exposed by following the twelfth subcostal nerve to T12–L1. Unless at least two levels are exposed with the approach, the visualization necessary to perform total discectomy, vertebrectomy, and strut grafting is extremely poor compared with the anterior approach.

A third approach that may be used in special situations is the tenth rib thoracolumbar approach for long exposures of the thoracic and lumbar spine. This approach allows proximal and distal extension for multilevel operations and optimum exposure for bony work.

TENTH RIB THORACOABDOMINAL APPROACH

Place the patient in the lateral decubitus position. Make the approach from the convexity of the scoliosis or from the left side, when possible (Fig. 138.15). A left-sided approach is preferred because of ease of mobilization of the aorta compared with the vena cava and because splenic retraction is easier than hepatic reconstruction. Open the skin and subcutaneous tissue from the lateral border of the paraspinous musculature over the tenth rib to the junction of the tenth rib and costal cartilage (20). Curve the incision anteriorly from the tip of the tenth rib to the lateral rectus sheath and distally down the edge of the sheath as far as necessary for exposure. Use electrocautery to slowly extend the incision through each muscle layer while an assistant aggressively picks up bleeders with two Adson forceps.

Open the superficial periosteum of the tenth rib to the costal cartilage. Use the sharp, curved periosteal elevator to remove the superficial and deep periosteum off the rib. Take care to avoid the neurovascular bundle on the inferior surface of the rib. Cut posteriorly at the angle of the rib, and cut at the junction of the rib and costal cartilage. Remove the rib. On opening the pleural space, retract the lung and fully open the rib bed with scissors (Fig. 138.16). At this point, the intrapleural cavity is opened and the retroperitoneal cavity is still closed.

Split the costal cartilage with a knife along its length. Open the undersurface of the costal cartilage and retract the two tags of cartilage (5,6,20) (Fig. 138.17). At this point, the intrapleural cavity is opened and the retroperitoneal cavity is still closed.

Identify the peritoneum and retroperitoneal space by blunt dissection under the retracted split tips of the costal cartilage. The guide to the retroperitoneal space is the light areolar tissue of the retroperitoneal fat (Fig. 138.18).
For the retroperitoneal exposure of the lumbar spine, an anterior pararectus vertical incision, a J-shaped renal incision, or a horizontal lateral abdominal incision can be used. I prefer the horizontal oblique incision.

For work on T2–L1, resect the diaphragm to the spine. Cut the crus of the diaphragm and elevate it off the spinal column. Use protected Deaver retractors to retract the peritoneal sac anteriorly. Identify the psoas muscle with its most cephalad attachment to the transverse process of L, and protect the muscle because the lumbosacral plexus is under it. With a large rib retractor, such as the Feochetti, open the tenth rib incision in the chest. The spine will be visualized from approximately T-5 as far distally in the lumbar spine as necessary. In the lumbar spine, remove the crus of the diaphragm and the attachments of the psoas muscle, if needed, for proper visualization of the spine. In the thoracic spine, the parietal pleura is opened as in a standard thoracotomy approach. Tie and ligate the intercostal artery and vein to allow mobilization of the major vascular trunks. If it is identified as in the operative area, the thoracic duct, which usually crosses right to left around T4–T5, is tied off. Avoid the sympathetic plexus. After the intercostal vessels are removed, cut directly to the spine. Dissection is carried out on the spine, and soft tissue is removed laterally.

After the peritoneum is retracted, carefully open the abdominal musculature (the external oblique, the internal oblique, and the transversus abdominis) one layer at a time, with complete hemostasis. At this point the chest and retroperitoneal space are open and the diaphragm is the intervening structure in the wound. Incise the diaphragm from inside the chest with clear visualization under the diaphragm in the retroperitoneal space. Extend the incision in the diaphragm circumferentially, 1 inch from its peripheral attachment to the chest wall (28). Use marker clips throughout the take-down of the diaphragm to allow accurate reapproximation.

For work on T2–L1, resect the diaphragm to the spine. Cut the crus of the diaphragm and elevate it off the spinal column. Use protected Deaver retractors to retract the peritoneal sac anteriorly. Identify the psoas muscle with its most cephalad attachment to the transverse process of L, and protect the muscle because the lumbosacral plexus is under it. With a large rib retractor, such as the Feochetti, open the tenth rib incision in the chest. The spine will be visualized from approximately T-5 as far distally in the lumbar spine as necessary. In the lumbar spine, remove the crus of the diaphragm and the attachments of the psoas muscle, if needed, for proper visualization of the spine. In the thoracic spine, the parietal pleura is opened as in a standard thoracotomy approach. Tie and ligate the intercostal artery and vein to allow mobilization of the major vascular trunks. If it is identified as in the operative area, the thoracic duct, which usually crosses right to left around T4–T5, is tied off. Avoid the sympathetic plexus. After the intercostal vessels are removed, cut directly to the spine. Dissection is carried out on the spine, and soft tissue is removed laterally.

The key to closure is the reapproximation of the costal cartilage. After the diaphragm is resutured with multiple interrupted sutures and the split cartilage is reapproximated, insert the chest tube in the eighth intercostal space and pass it posterosuperiorly. Attached to the cephalad half of the costal cartilage is the insertion of the peritoneum and the interthoracic fascia. Inserting into the distal split of costal cartilage is the transverse abdominal fascia and attachment for the abdominal musculature. With the costal cartilage reapproximated, the layers of the abdominal musculature are better defined. Close each layer of the abdominal wall separately when possible, and close the chest as in a standard thoracotomy.

**THE LUMBOSACRAL SPINE**

**PARARECTUS INCISION FOR L2–S1**

- Position the patient supine on the table with the lower lumbar spine at the level of the kidney rests.
- Make a lower abdominal pararectus incision through the skin and subcutaneous tissue. The most immediate layers are those of the external oblique with its transition into the linea semilunaris, which leads to the fascia of the rectus sheath. The linea semilunaris is composed of the aponeurosis of the three layers of the abdominal musculature and their fascia.
- Incise the fibers of the external oblique, the internal oblique, and the small thin layer of transversus abdominis muscles laterally to the semilunaris in line with the skin incision.
- Identify the transversalis fascia, which is the internal investing fascial layer of the abdominal cavity. Dissect the outer surface of the transversalis fascia to the edge of the rectus sheath. The transversalis fascia splits at this point to form the lamina of the rectus sheath. The posterior lamina of the rectus sheath forms the endoabdominal fascia in this area.
- Carefully incise the transversalis fascia laterally to the linea semilunaris, and identify the peritoneum through the incision.
- Begin the incision in line with the skin incision. Dissect the peritoneum with a sponge or gloved hand off the undersurface of the transversalis fascia. Open the abdominal wall after the peritoneum has been identified and cleared.
- Bluntly dissect the peritoneum from the lateral abdominal wall, progressing posteriorly. Identify the psoas muscle, as in any retroperitoneal approach to the spine. Retract the peritoneum off the left iliac artery and vein by use of the surgeon’s hand, a padded deaver retractor, or sponge sticks. Sweep the peritoneum with the ureter from left to right, and expose the left common iliac artery and vein. Insert Freebody pins or special retractors.
- Palpate and identify the intervertebral disc. Remember that this is a relatively avascular area. With any approach to the L4–S1 area, identify the left iliolumbar vein and ligate it when necessary. Dissection within the bifurcation of the aorta should be blunt and as avascular as possible. Remember, the left common iliac vein lies in the bifurcation over the L4–S1 disc. The variation in inferior vena cava and lumbar veins often dictates the exact approach from this point.
- Bluntly retract and protect the hypogastric plexus.
- Allowing the peritoneal sac to fall into place, close the muscle layers with a running suture. The transversus abdominis and the internal oblique may be closed together.

**ANTERIOR RETROPERITONEAL FLANK APPROACH TO L2–L5**

For the retroperitoneal exposure of the lumbar spine, an anterior pararectus vertical incision, a J-shaped renal incision, or a horizontal lateral abdominal incision can be used. I prefer the horizontal oblique incision...
Place the patient in the supine position over the kidney rests. For patients with a large abdominal pannus, the left lateral decubitus position can be used. In the lateral position, too much hip flexion at this point will limit the operative exposure anteriorly.

Start the incision equidistant between the lowest rib and the superior iliac crest in the midaxillary line, and extend it approximately to the edge of the rectus sheath. The level of the incision varies according to the level of the spine approached: L5–S1 is in the lower half of the distance between umbilicus and symphysis, L4–5 is in the upper half, L3–4 is at the umbilicus, and L2–3 is above the umbilicus. The length of the incision can vary according to the surgeon's experience, the exposure needed, and the operation to be done.

Muscle relaxation allows greater mobility to the abdominal wall and decreases the controllability of the muscle as it is incised. First, open the muscle layers as laterally as possible because they are thicker here and there is less chance of penetrating the peritoneum. The muscle layers thin out, and the layers of the fascia become almost joined medially. The peritoneum is very superficial. Inadvertent penetration of the peritoneum is most likely just lateral to the rectus sheath. Dissect through the external oblique and the internal oblique muscle. Inferior to the internal oblique is the transversus abdominis. Use care in inserting self-retaining retractors into the muscle layers so as not to damage the peritoneum. Often, the transversus abdominis muscle is a very thin or absent muscle layer. Bluntly spread the thin muscle in line with its fibers to expose the transversalis fascia.

Open the transversalis fascia in the lateral portion of the wound (Fig. 138.21). Lift the transversalis fascia with Adson forceps and carefully open it with blunt scissors. The retroperitoneal fat allows room to enter the extraperitoneal space.

Enter the retroperitoneal space laterally. Identify the peritoneum and the fat of the peritoneal space. Remove the peritoneum from the remaining transversalis fascia with blunt dissection. Extend the incision after the peritoneum has been safely removed. The sheath may be incised for added exposure. Torn peritoneum should be repaired promptly (19).

Identification of the psoas muscle is the key to the retroperitoneal approach. Pass your hand directly to the psoas. Avoid opening the retroperitoneal space, which is a blind pouch. The genitofemoral nerve can be identified on the psoas. The spine is immediately medial to the psoas and can be partially obscured by it. Palpate and identify the psoas muscle, the intervertebral disc, the aorta, and the vertebral body. The paravertebral sympathetic chain lies medial to the psoas muscle. The ureter will be reflected medially with the undersurface of the peritoneum. If a retroperitoneal abscess is well developed, open it and dissect inside the abscess to the spine.

The key at this point is to identify the raised, white, softer disc by direct palpation with the finger, as opposed to the lower, concave vertebral body, where the lumbar vessels are found. The discs are the hills, and the vertebral bodies are the valleys. The vessels are in the valleys.

Once the lumbar disc can be identified, insert a blunt elevator or padded small retractor to sweep the soft tissue from left to right across the disc space. The lumbar veins are a horizontal tether. Variations in formation of the inferior vena cava and lumbar veins are the rule rather than the exception (11). The most important of these veins is the iliolumbar vein, which crosses the body of L-5 from right to left and ascends in the left paraspinal area (13). This vessel is a direct tether to the left-to-right retraction of the aorta off the spine and is very vulnerable to avulsion.

For operations on the L4–L5 disc space, identify the iliolumbar vein early in the dissection (Fig. 138.22). Ligate it after clamping the vein with angled tonsil clamps and passing two or three ligatures around the vein. These ligatures should not be tied too close to the vena cava because a sidewall injury can occur. Transect the vein after securing the permanent ties. Greater mobilization of the vena cava and venous structures, left to right, is thereby obtained. The iliolumbar vein consistently requires ligation.

Lumbar veins of varying sizes at various positions are always present. Some may be directly posterior to the vena cava and of quite large diameter. Dissection on the anterior spine consists of gentle stretching and pulling of the structures, blunt dissection, direct pressure over many small bleeding areas with a sponge, and a minimum of electrocautery. The paraspinal sympathetic plexus between the spine and the psoas muscle varies in size and number of fibers. Branches course between the paraaortic and paraspinal chains. Preserve paraspinal sympathetic fibers that do not impede dissection.

Dissect with the fingertip and blunt elevators all the vascular structures from left to right to give adequate visualization of the end plate of the vertebral body above the disc (27).

Use malleable Deaver-type retractors or blade spike retractors around the disc space. Alternatively, prepare four Freebody Steinmann pin retractors with rubber sleeves and mount them in a Steinmann pin holder (9). For any sharp stay-retractor that is driven into the body, stabilize the pin on the finger and engage the tip into the vertebral body under direct vision. The assistant taps the pin into the body while the surgeon maintains control of the pin. Avoid the tendency for the pin to enter the disc space by directing the tip of the pin horizontal to the disc space. Allow a sufficient distance from the endplate to allow work on the disc space without dislodging the pin. Place the superior and inferior right-sided pins before placing the left-sided pins.

Expose the annulus of the disc (Fig. 138.23). There should have been minimal sharp dissection and cautery in this area. Now prepare the disc for the operative procedure. The transversalis fascia and iliac artery and vein are held by the retractors.
When making the incision, follow the skin guidelines for optimum spine exposure. Until the annulus of the disc is clearly exposed, make no transverse scalpel cuts on the front of the L5–S1 disc. Attempt to retract the middle sacral artery and vein without electrocautery by spreading and blunt dissection. Use vascular clips or tie ligation when this vessel is encountered. Identify the raised, soft, white disc. Beware of thinning muscle layers and the peritoneum's superficial position medially near the rectus sheath. Pass directly to the psoas muscle. Identify, ligate, and divide the iliolumbar vein. Incise the transversus abdominus muscle layer and the transversalis fascia in the lateral portion of the wound. For the transperitoneal midline approach, carefully open the posterior peritoneum and bluntly dissect the prevertebral tissue from left to right. Achieve careful hemostasis in the muscle layers. Insert the Steinmann pin after placing it directly on bone with the fingertip. Remove the prevertebral tissue from the L5–S1 disc with blunt dissection, retraction, and spreading. Visualize and retract the prevertebral tissues by opening the posterior peritoneum higher over the bifurcation and then extending the opening down over the posterior rectus sheath, the abdominal fascia, and the peritoneum are conjoined in this area. Carefully open the posterior rectus sheath and abdominal fascia to provide adequate exposure of the retroperitoneal structures.Palpate the spine with a finger and find a disc for orientation. Usually, it is the L4–L5 disc. With identification of the L4–L5 disc, palpate the pulse of the left common iliac artery and the aortic bifurcation. The bifurcation of the aorta is critical in determining the exact approach from this point. The usual bifurcation at the L4–L5 disc level was present in 69% of anatomic dissections performed by Harmon (11), but great variation exists. Palpate the left common iliac artery and pass over it medially to the L5–S1 disc. By placement of the finger and a subsequent blunt retractor such as a posterior retractor from the left side of the L5–S1 disc, achieve care enough to retract the iliolumbar vein by blunt dissection. The left iliolumbar vein lies within the aortic bifurcation. It often courses directly on the surface of the L5–S1 disc and may be flattened against the disc or L–5 body, with its venous character obscured. Mobilize it to the left and cephalad with the left iliolumbar artery. The middle sacral artery and veins are present in the bifurcation. The key to handling these structures is blunt dissection just to the right of the left common iliac artery, sweeping from left to right to the prevertebral tissue, including the middle sacral vessels and superior hypogastric plexus, off the lumbosacral disc. Occasionally, the middle sacral vessels are of formidable size, but seldom do they have to be ligated (4). An additional structure in the bifurcation is the superior hypogastric sympathetic plexus. The thoracolumbar sympathetic chain extends down anterior to the aorta and vertebral bodies in the retroperitoneal space as the preaortic sympathetic plexus. At approximately the L3–L4 level, the inferior hypogastric plexus extends to L4–S1 as the superior hypogastric plexus. The structure of the superior hypogastric plexus varies considerably because the preponderance of the superior hypogastric plexus fibers is usually closer to the left iliac artery as they arch over the L5–S1 disc in the bifurcation of the aorta. There may be multiple strands or one predominant large simple nerve trunk. The superior hypogastric plexus contains the sympathetic function for the urogenital system. The S1–S4 nerve roots that contribute to the pelvic splenic nerves provide parasympathetic function for the urogenital system. The pudendal nerve covers somatic function from S-1, S-2, S-3, and S-4.

**RETROPERITONEAL EXPOSURE OF L5–S1**

- Palpate the spine with a finger and find a disc for orientation. Usually, it is the L4–L5 disc. With identification of the L4–L5 disc, palpate the pulse of the left common iliac artery and the aortic bifurcation. The bifurcation of the aorta is critical in determining the exact approach from this point. The usual bifurcation at the L4–L5 disc level was present in 69% of anatomic dissections performed by Harmon (11), but great variation exists. Palpate the left common iliac artery and pass over it medially to the L5–S1 disc. By placement of the finger and a subsequent blunt retractor such as a posterior retractor from the left side of the L5–S1 disc, achieve care enough to retract the iliolumbar vein by blunt dissection. The left iliolumbar vein lies within the aortic bifurcation. It often courses directly on the surface of the L5–S1 disc and may be flattened against the disc or L–5 body, with its venous character obscured. Mobilize it to the left and cephalad with the left iliolumbar artery. The middle sacral artery and veins are present in the bifurcation. The key to handling these structures is blunt dissection just to the right of the left common iliac artery, sweeping from left to right to the prevertebral tissue, including the middle sacral vessels and superior hypogastric plexus, off the lumbosacral disc. Occasionally, the middle sacral vessels are of formidable size, but seldom do they have to be ligated (4).

- An additional structure in the bifurcation is the superior hypogastric sympathetic plexus. The thoracolumbar sympathetic chain extends down anterior to the aorta and vertebral bodies in the retroperitoneal space as the preaortic sympathetic plexus. At approximately the L3–L4 level, the inferior hypogastric plexus extends to L4–S1 as the superior hypogastric plexus (Fig. 138.24). The structure of the superior hypogastric plexus varies considerably because the preponderance of the superior hypogastric plexus fibers is usually closer to the left iliac artery as they arch over the L5–S1 disc in the bifurcation of the aorta (Fig. 138.25). There may be multiple strands or one predominant large simple nerve trunk. The superior hypogastric plexus contains the sympathetic function for the urogenital system. The S1–S4 nerve roots that contribute to the pelvic splenic nerves provide parasympathetic function for the urogenital system. The pudendal nerve covers somatic function from S-1, S-2, S-3, and S-4.

**Ejaculation is predominantly a sympathetic function, whereas through control of the vasculature of the penis, erection is predominantly a parasympathetic function.** Retrograde ejaculation and sterility result from disruption to the sympathetic plexus. The main effect of damage to the superior hypogastric plexus is improper closing of the bladder neck, with resultant retrograde ejaculation, although the sympathetic fibers also have some effect on the motility of the vas deferens, which is important in the transportation of the spermatozoa from the epididymis to the seminal vesicle (15). The prognosis for recovery from retrograde ejaculation is good (6). Sperm can be obtained in refractory cases by bladder aspiration techniques. Damage to the superior hypogastric plexus should not produce impotence or failure of erection. Avoid damaging the hypogastric plexus by doing the following (4):

1. For the transperitoneal midline approach, carefully open the posterior peritoneum and bluntly dissect the prevertebral tissue from left to right (6).
2. Visualize and retract the prevertebral tissues by opening the posterior peritoneum higher over the bifurcation and then extending the opening down over the iliac promontory (4, 9, 13, 15).
3. Remove the prevertebral tissue from the L5–S1 disc with blunt dissection, retraction, and spreading.
4. Attempt to retract the middle sacral artery and vein without electrocautery by spreading and blunt dissection. Use vascular clips or tie ligation when this vessel is of considerable size.
5. Until the annulus of the disc is clearly exposed, make no transverse scalpel cuts on the front of the L5–S1 disc.
6. Do not use electrocautery within the aortic bifurcation.

The key to avoid damaging the superior hypogastric plexus is to avoid transverse cuts on the face of the disc until all the prevertebral tissue has been elevated from the annulus and to avoid electrocautery on the surface of the L5–S1 disc. Small bleeding points are encountered when doing this dissection, but they are usually easily controlled by direct finger pressure or packing with hemostatic gauze. Usually, the left iliolumbar artery and vein will be retracted to the left, but it may require retraction to the right on occasion.

- Locate and ligate the iliolumbar vein before any mobilization of the left iliolumbar artery to the right.
- Always obtain radiographic confirmation of the level. It can be done easily by inserting a #22-gauge spinal needle and taking a radiograph. Because the L5–S1 disc and the sacrum are often angled very horizontally, the body of L-5 can be mistaken for the sacrum.
- Insert appropriate Freebody Steinmann pin stay-retractors, blade-point retractors, or hand-held retractors.

**TRANSPERITONEAL EXPOSURE OF L5–S1**

- For the transperitoneal exposure, use either a vertical midline incision or a transverse "smile" incision. The "smile" is better cosmetically and gives excellent exposure, but it requires transection of the rectus abdominus sheath. Identify and open the rectus sheath, and transect the rectus abdominus muscle. The posterior rectus sheath, the abdominal fascia, and the peritoneum are conjoined in this area. Carefully open the posterior rectus sheath and abdominal fascia to provide adequate exposure of the retroperitoneal structures.
the peritoneum.

- Pick up the peritoneum. Open the length of the wound carefully, avoiding damage to the bowel. Identify the posterior peritoneum over the sacral promontory after packing off the bowel.
- Palpate the aorta and both iliac vessels through the posterior peritoneum. Feel the softer texture of the L5–S1 disc.
- Inject the retroperitoneal space with saline to achieve separation of the peritoneum from the vascular structures.
- Pick up the peritoneum with Adson forceps; handle it delicately.

Avoid use of the electrocautery anterior to L5–S1 to prevent damage to the superior hypogastric plexus, despite the fact that there is bleeding in this area. The left common iliac vein often lies as a flat, white, bloodless ribbon across the L5–S1 disc within the aortic bifurcation.

- After the left common iliac artery and left common iliac vein are identified, use blunt dissection to the right of the left iliac artery and hypogastric plexus and soft tissue, moving from left to right (Figs. 138.26).

![Figure 138.26. Exposure of the L5–S1 disc. See text for a description of the technique.](image)

- Bluntly dissect the middle sacral artery and vein from left to right without sacrifice at this point. Longitudinal blunt dissection allows better mobilization of these vascular structures. When bleeding is encountered, use direct finger and sponge pressure for a short time, followed by blunt dissection. Control hemorrhage with packing and pressure. Divide and tie the middle sacral artery and vein, if necessary.

POSTERIOR APPROACH TO L1–S1

- Position the patient to allow full chest excursion, to maintain the neck in a safe position, and to allow the abdomen to hang completely free of pressure. Flex the hips and knees enough to relieve nerve root tension but not so much as to obstruct arterial flow to the legs or to produce any abdominal pressure. I prefer the Andrews frame.
- Obtain a skin marker radiograph by inserting two #20-gauge spinal needles perpendicular to the skin approximately three fingerbreadths lateral to the spine. Using the alignment of the needles, put the skin incision in the midline over the disc space. Paraspinal needles allow a more accurate skin incision than a spinal process marker.
- Use a skin marking pencil to draw a vertical, midline skin incision relative to the two needles over the disc space. Make a dermal skin incision only.
- Use a Cobb elevator, with the tip turned upward, onto the spinous process just under its bulbous tip, and start the subperiosteal dissection. Then turn the elevator bevel down. Dissect, identify by touch the cephalad and then the caudad lamina, and clear the interlaminar area. Take care not to cut through the outer cortex of the lamina. Sweep the superficial soft tissue off the interlaminar area laterally out to the facet joint capsule. Do not damage the capsule. Protect the facet joint capsule. Remember that the two laminae and their interlaminar areas are the only areas that need be exposed for an operation on one intervertebral disc.
- Following exposure of the intralaminar area, place a Williams self-retaining retractor with the blade retracting laterally over the facet joint capsule with the pointed tip placed medially. For larger, bilateral exposures, I use the Wiltse retractors with both sides exposed similarly.
- The superficial ligamentum flavum blends laterally into the facet joint capsule. Incise the superficial ligamentum flavum with the #15 blade or electrocautery laterally or at the junction of the superficial ligamentum flavum and the facet joint capsule. Use a curet to elevate the superficial ligamentum flavum from the deep ligamentum flavum and its insertion on the lamina.

![Figure 138.27. This underview of the posterior elements from the intervertebral canal demonstrates the ligamentum flavum and its insertion on the lamina.](image)

- Several factors concerning the anatomy of the ligamentum flavum are important:
  - It has a deep and superficial portion.
  - It blunts with the facet joint capsule laterally.
  - It inserts over the caudal 50% of the undersurface of the cephalad lamina.
  - It blends with the facet joint capsule laterally.
  - It inserts on the cephalad edge of the caudad lamina.
  - Its undersurface is the ideal dural covering.
  - It has a vertical, parasagittal orientation deep in the lateral recess under the superior facet that may contribute to lateral recess stenosis.
  - It is the main stabilizing ligament of the posterior column, and preservation of as much of it as possible will benefit spine stability at that motion segment.
  - It is the soft-tissue roof of the intervertebral foramina.

LAMINOTOMY

- Perform as much of the lateral wall resection and laminectomy as possible before opening the ligamentum flavum. Estimate the size of the interlaminar area that will be needed for correcting the pathologic process. A portion of the caudal edge of the cephalad lamina can be removed if it is believed that exploration of the spinal canal will require greater cephalad exposure. The walls of the interlaminar area may be the area to be removed. Progressing from dorsal to ventral, the lateral wall of the interlaminar area is composed of the facet joint capsule, the inferior facet, the intra-articular space of the facet joint, the superior facet, the deep capsule and ligamentum flavum, the nerve root, the blood vessels, and the floor of the canal. The preoperative CT scan should determine the amount of lateral recess stenosis and how much of a medial facetectomy is needed. Remove as much bone as necessary. For a standard LS–S1 discectomy, I seldom remove any bone. At L3–L4, a centimeter of cephalad lamina is often removed. Evaluate the CT scan for cephalad migration of a disc fragment that would require the removal of more lamina. To allow a more lateral approach to a larger extruded disc fragment, remove a small portion of the medial facet. More extensive exposure may be required depending on the pathology.
- For a discectomy, make an incision with a #15 blade into the deep portion of the ligamentum flavum, approximately 50% of the width of the interlaminar area. Incise the ligamentum flavum by feathering the knife blade, allowing one to see the edge of the knife cutting into the ligamentum flavum. Make the incision by long cuts into the ligamentum flavum reaching from lamina to lamina with careful observation for any sign of the white undersurface of the ligamentum flavum, followed by the bluish hue of the dura. Once the undersurface is reached, use the handle of the knife or a Penfield 4 elevator to open the last few underlayers of the

Several factors concerning the anatomy of the ligamentum flavum are important:

- It has a deep and superficial portion.
- It blunts with the facet joint capsule laterally.
- It inserts over the caudal 50% of the undersurface of the cephalad lamina.
- It blends with the facet joint capsule laterally.
- It inserts on the cephalad edge of the caudad lamina.
- Its undersurface is the ideal dural covering.
- It has a vertical, parasagittal orientation deep in the lateral recess under the superior facet that may contribute to lateral recess stenosis.
- It is the main stabilizing ligament of the posterior column, and preservation of as much of it as possible will benefit spine stability at that motion segment.
- It is the soft-tissue roof of the intervertebral foramina.
ligamentum flavum. Use the Penfield 4 elevator to separate the entire length of the ligamentum flavum. Under the ligamentum flavum is usually a layer of epidural fat over the dura, but with a large space-occupying lesion in the canal, the dura may be immediately adjacent to the undersurface of the ligamentum flavum. Pass the Penfield 4 elevator under the lateral leaf of the ligamentum flavum, and retract the dura medially away from the lateral leaf of the ligamentum flavum. A cottonoid placed laterally under the lateral leaf of the ligamentum flavum and retracted medially may help. In the other hand, pass the Kerrison rongeur under the lateral ligamentum flavum and remove the lateral ligamentum flavum.

- The epidural fat, the dura, the nerve root, and the longitudinal blood vessels in the lateral recess can usually be identified after the lateral half of the ligamentum flavum is removed. The deep portion of the ligamentum flavum runs vertically in the lateral recess and attaches to the facet joint capsule. Position the cottonoid or Penfield 4 elevator between this portion of the ligament and the underlying nerve root. This stage of entering the canal is often an anxious one because of fear of bleeding and damaging the nerve root. The more delicate the approach, the less bone that is cut, and the less vigorous the removal of the lateral ligamentum flavum, the less bleeding there will be. Magnification is of tremendous value in identifying vessels and allowing safe, accurate retraction and bipolar coagulation, if needed. Removal of fat causes bleeding and later scarring. Bleeding often starts when exposing the disc or nerve root. When lateral exposure is obtained to the pedicle, the longitudinal vessels lateral to the root can be identified and cauterized with the bipolar cautery. Cottonoids placed laterally at the cephalad and caudal extremes of the exposure can collapse the vessels and allow work in the area between the cottonoids.

- A transverse or horizontal vascular supply exits each intervertebral foramen. The most consistent vascular leach is found just caudal to the nerve root exiting in the caudal portion of the intervertebral foramen at the cephalad portion of the disc. For large exposures, when the dural sac needs to be retracted to the midline, identify the pedicle, reflect by bisecting the lateral leaf of the ligamentum flavum, and then remove the ligamentum flavum. This is especially useful for large, more posterior disc herniations.

- The use of cottonoids, Surgicel, and thrombin-soaked Gelfoam retards bleeding. I prefer not to leave Gelfoam and Surgicel packing in the spinal canal. Cottonoids remove epidural fat and should be used judiciously.

Fig. 138.28. The pedicle is the key to the intracanal anatomy. Identification of the pedicle will lead to the location of the disc and nerve root.

Knowing the location of the pedicle tells you the following:

- The disc space is less than 1 cm cephalad to the pedicle. It often appears to be immediately cephalad adjacent to the pedicle.
- The intervertebral foramen above the pedicle is for the exiting nerve root and the intervertebral foramen below the pedicle is the foramen for the transversing nerve root.
- Dorsal and immediately cephalad to the pedicle is the superior facet. The superior facet is the roof of the intervertebral foramen for the exiting nerve root.
- Just medial to the pedicle is the traversing nerve root.
- Extensive probing should not be done in the medial pedicular area because the pedicular plexus will bleed. Remember, at higher lumbar levels, the disc is farther cephalad relative to the interlaminar space. Therefore, the L5-S1 disc is approximately at the level of the interlaminar space between L-5 and S-1. The L2-L3 disc space is well cephalad under the lamina of L-2 rather than at the level of the interlaminar space between L-2 and L-3. The ligamentum flavum covers the interlaminar area.

It is often imperative to expose the disc space. The disc is a raised, white, soft structure that may be covered by epidural fat, veins, and the nerve root. Feel for the disc using the Penfield 4 elevator. It causes little bleeding and allows for palpation of the disc with the tip of the instrument. Reach out laterally and feel for the floor of the canal. Gently retract medially with the Penfield 4 elevator. Feel for obstruction to this medial retraction. Do not retract against a major obstruction. Retract gently, and insert the microscissor retractor. Lift the root up and medial with the nondominant hand; expose the disc with the Penfield 4 elevator in the dominant hand.

When there is difficulty in finding the disc or retracting the nerve root, several methods have been used to prevent damage to the nerve root. Knowing the location of the pedicle in the canal is probably the most significant way to avoid major damage to the nerve root. Find the pedicle. The transversing nerve root is adjacent mediad to the pedicle. Identify the nerve root medial to the pedicle. If the root cannot be retracted because it is tightly against the medial wall of the pedicle, proceed cephalad to a point slightly lateral to the medial wall of the pedicle. The transversing nerve root should not be lateral to the medial wall of the pedicle. Exposing the disc cephalad to the pedicle and lateral to the medial wall of the pedicle can avoid nerve damage. The nerve root exiting in this intervertebral foramen cephalad to the pedicle will usually be further cephalad, just under the pedicle above. The exiting nerve root runs obliquely across the intervertebral disc laterally in or lateral to the intervertebral foremen. The farther lateral on the intervertebral disc, the more likely the cephalad exiting nerve root is reached. A lateral disc herniation may trap the exiting nerve root in the intervertebral foramen. A conjoined root may totally fill the entire foramen from pedicle to pedicle. An exiting conjoined nerve root limits exposure of the disc. It can usually be identified preoperatively on the myelogram and contrast CT scan. The key to avoiding damage to a conjoined nerve root is recognition. This is facilitated by lateral exposure of the traversing root shoulder.

For further exposure of the disc, determine the amount of tension in the nerve root. Do not retract the root against a solid obstruction. If it can be retracted easily, retract it medially with the nerve root retractor. If it is tight, it will feel like you are retracting against a solid wall.

There are five common methods of dealing with a tight nerve root:

1. Explore the axilla of the transversing root with the Penfield 4 elevator. The axilla is in the caudal part of the exposure between the root and the dural sac. If a fragment is found, remove it with the nerve hook. Bleeding may be encountered.
2. Obtain more lateral exposure. Be sure you have identified the pedicle and have exposure lateral to the medial wall of the pedicle. The traversing nerve root should not be lateral to the medial wall of the pedicle.
3. Enter the disc space lateral to the root, and try to decompress the disc and pull disc material from under the root through the disc space.
4. Be sure that the root is free cephalad to the disc and that the ligamentum flavum or undersurface of the cephalad lamina is not a factor. Remove enough lamina and ligament cephalad to expose the shoulder of the nerve root.
5. If the fragment is tethered caudally in the ligamentum flavum, remove the fragment as it exits around the pedicle. A foraminotomy of the foramen below may allow better retraction of the root.

Gently lift and retract the nerve root with a sucker retractor in the nondominant hand and explore the disc area with a nerve hook in the dominant hand. Take great care not to stretch the nerve root. Exploration underneath the dural sac may reveal a large fragment of herniated disc that can be pulled out from under the nerve root with the nerve hook. Exploration underneath the dural sac may reveal a large fragment of herniated disc that can be pulled out from under the nerve root. The lateral exposure allows this fragment of disc to be pulled laterally rather than vertically. Removing the fragment laterally from the spinal canal may trap the exiting nerve root in the intervertebral foramen. A conjoined root may totally fill the entire foramen from pedicle to pedicle. An exiting conjoined nerve root limits exposure of the disc. It can usually be identified preoperatively on the myelogram and contrast CT scan. The key to avoiding damage to a conjoined nerve root is recognition. This is facilitated by lateral exposure of the traversing root shoulder.

For further exposure of the disc, determine the amount of tension in the nerve root. Do not retract the root against a solid obstruction. If it can be retracted easily, retract it medially with the nerve root retractor. If it is tight, it will feel like you are retracting against a solid wall.

When a total laminectomy is needed to expose the dura and nerve roots, remove the fascia entirely from the tip of the spinous process bilaterally. Extend the exposure laterally from the spinous process to the lamina with the Cobb elevators. Carefully protect the facet joint capsule. The exposure may be to the tips of the transverse processes if a fusion is to be done.

Note: The most important structure that must not be exposed and clearly seen is the pars interarticularis. Identification of the pars is imperative to prevent its transection with subsequent spinal instability. By continuously visualizing the pars, removal of the lamina can be done quickly and safely. The bone cutters remove the spinous process. I prefer to use the Midas Rex AM1 (Midas Rex Pneumatic Tools, Inc., Fort Worth, TX) to remove all of the lamina over the ligamentum flavum, the lateral leaf of the ligamentum flavum, the spinous process, the lamina, and the part of the facet joint capsule. Alternatively, use the Luxel rongeur by inserting it under the caudal edge of the cephalad lamina and rotate the instrument cephalad, rolling a bite of lamina off. This allows visualization under the instrument to see a possible inadvertent dura pinch early. Before using the Midas Rex tool, I expose the pars by curetting the caudal tip of the inferior facet. Seeing the articular surface of the superior facet and the pars at each level allows full removal of lamina and medial portion of the facet without danger of cutting the pars. Identify the pedicle as soon as possible to avoid removing too much bone.
much facet.

- To expose the lateral portion of the spinal canal, remember that the lateral wall may protrude significantly into the spinal canal. If the partial medial facetectomy is to be done, use the Midas Rex AM1 or AM3, the Kerrison rongeur, the Cloward chisel, or the Pheasant discotome. Starting medially on the lamina, cut the caudal portion of the lamina and continue laterally onto the inferior facet. The amount of inferior facet removed varies according to the pathology. If the chisel is used, insert it to remove the appropriate amount of the medial portion of the inferior facet and twist the chisel, removing the bone medially. This allows visualization of the facet join space and the superior facet. The shiny cartilaginous floor is the superior facet. The ligamentum flavum inserts on the superior facet. The nerve root exits under this angle.

- The ligamentum should be opened at this point by one of several methods. Use the curet to detach the lateral ligamentum flavum from the edge of the superior facet. Position the Penfield 4 elevator, Penfield 3 elevator, or the cottontoid under the superior facet to protect the nerve. Use the Kerrison rongeur to remove the medial portion of the superior facet and the most lateral ligamentum flavum. The chisel is quite safe on the lateral face because the superior facet provides a guard from possibly injuring the nerve root. With skill and experience, the superior facet likewise can be removed with a chisel by cutting over the pedicle with the Penfield elevator, protecting the nerve. With lateral recess stenosis, remove the medial facet to the parasagittal level of the medial wall of the pedicle.

- To expose the foramen, cut the pedicles. If the Midas Rex bone cutter is used, this can be done because it causes less splintering. Cut the lamina down centrally with the AM1. With the AM3, extend the bone removal laterally over the ligamentum flavum and foramen.

- After the lamina is burrowed down to a thin layer over the dura and totally off the ligamentum flavum, open the ligamentum with a Penfield 3 elevator and clasp it with a ligature. Pick up the caudal port of this dura and the dura. Remove the top of the ligamentum flavum with a large, straight curet from the opposite side of the table. The most lateral ligament is removed by undercutting with the angled Kerrison chisels from the side table. Position the cottontoid and have the assistant remove the ligamentum flavum with a 45° Kerrison rongeur from the other side of the table. Remove the medial edge of the superior facet with the lateromedial ligamentum flavum. The assistant on the opposite side of the table also can position the 45° Kerrison rongeur to remove this lateral portion of the ligamentum flavum.

- The ligamentum flavum can be detached with a curet from its caudal and lateral attachments, and a curved osteotome can be used to free the cephalad attachment of the ligamentum flavum from the undersurface of the cephalad lamina. Use a nerve hook to pull the detached cephalad edge of the ligamentum flavum into the intralaminar area. Use a straight curet to detach the caudal edge of the ligamentum flavum from the edge of the caudal lamina and an angled curet to detach the lateral ligamentum flavum. With this method, the ligamentum flavum can be retracted intact with a medial attachment to the ligamentum flavum from the opposite side, allowing access to the spinal canal without excision of the ligamentum flavum. Although the ligamentum flavum, being elastic, will shrink from its original attachment, it will still provide an excellent dural covering when reapproximated on closing. There is some danger in detaching this ligamentum flavum in the lateral recess because of the nerve root. Be careful over the “critical angle,” which is the junction of the base of the superior facet and the caudal lamina, because the nerve root exits under this angle.

FORAMINOTOMY

- The key to a safe, effective foraminotomy is to expand the intervertebral foramen without damaging the pars interarticularis or the facet joint. A foraminotomy begins after removal of the lateral recess, identification of the pedicle, and identification of the pars interarticularis. The medial caudal aspect of the pedicle is the beginning of the intervertebral foramen. The pars forms part of the bony roof of the intervertebral foramen. The root exits around the pedicle, and it is the root over that root that must be expanded. I use the Midas Rex AM3 to an arc over the root below the root and over the root and plenty of the facet undersurface. Then insert the Kerrison rongeur on the root and remove the bone touching the nerve and any ligamentum flavum attached to it. Probe the foramen until it is clear. I use quillabral probes up to 5 mm in diameter or a Woodson probe. Often, the tip of the superior facet compresses the nerve root from below. I routinely remove the cephalad tip of the superior facet with the Cloward chisel. The curved Kerrison rongeur removes more of the roof of the foramen laterally. Protect the pedicle. A portion of its undersurface can be carefully expanded to open the intervertebral foramen.

- Uncinate ventral spurs may arise from the cephalal vertebral body, caudal to the pedicle, at the edge of the disc space below; they are seen on CT foraminal reconstructions. The root can be torted over the spur and tethered laterally by foraminal ligaments. Removing the root is not enough to relieve this nerve root tension. The spur under the root should be removed. Although these spurs can be removed from cephalad to caudal by pulling a chisel under the root, they are more easily approached from the level below. Remember, these spurs are under the annulus of the disc below and covered with soft tissue, making removal with a chisel more difficult. Pulling a knife under the nerve root is dangerous.

- Expose the disc below. Working from cephalad to caudal, identify the exiting root. Open the disc with a knife laterally. Use the chisel and curet to burrow under the spine and then the endplate of the vertebra. Hollow out a space. Insert an angled curet between the root and the annulus-covered spur, and knock the spur out of the hole. Leave it in the hole or remove it. If it is safer to remove it after the root tension is relieved.

- The foraminotomy can be performed from the “outside in.” Move to a paraspinous position through the same incision. Identify the superior facet and transverse process above and below the pedicle. Several smalls can be taken from this part. One is to remove the intertransverse ligament, identify the nerve, and follow it back to the proper exit. Any obstructions due to the caudal surface of the pedicle above, using the cephalad surface of the pedicle as guides. Identify the nerve there and expand the intervertebral foramen. If there is a foraminal hemiated nucleus pulposus, expose the cephalad surface of the pedicle below, and cephalad, identify the disc, the nerve, and the hemiation.

- After the discectomy, the delicacy of the approach will determine how much fat is left covering the nerve root. Supplement this procedure with a free fat graft taken from the layer above the fascia in the caudal portion of the wound. When fat is not available, I use Depo-Medrol–soaked Gel foam.

- After closing any dead space left by the fat graft, close the fascia with interrupted 0 Vicryl. When midline fascial structures have been removed from the spinous process, reattach them. The layers above the fascia are closed with multiple layers of interrupted 2-0 Vicryl. Close the subcutaneous fat in at least two layers, backing each layer to the lower layer. I usually drain both the subfascial and suprafascial layers. Close the subcutaneous layer immediately adjacent to the subcuticular layer. Close the skin with subcuticular sutures, benzoin, and Steristrips. Retract and cut off the sutures after the Steristrips are applied.

LATERAL APPROACH TO THE DISC

- Position the patient on a standard operating frame.

- Use two needles to identify the pedicles of the involved segment with a lateral radiograph. For L4–L5, align the needle markers over the pedicle at L-4 and the pedicle at L-5. Make the incision one fingerbreadth lateral to the spinous process, spanning between the pedicles of the involved segment (Fig. 138.29).

Figure 138.29. Make the incision one fingerbreadth lateral to the spinous process, spanning between the pedicles of the involved segment.
Remember:
  Follow the nerve laterally to insure removal of any lateral disc fragments.

Identify the caudal aspect of the nerve and use the microsucker retractor to retract the nerve cephalad. Using the Penfield 4 elevator, identify the disc caudal to the nerve. Be aware that the dorsal ganglion of the nerve may feel like a disc fragment under the nerve. Carefully identify the nerve and the disc (Fig. 138.31).

Use the Penfield 4 elevator to palpate gently cephalad to the nerve, starting at the medial wall of the pedicle and progressing laterally. Beware of bleeding in this area.

Identify the cephalad transverse process, then expose the part interarticularis medially. Detach the intertransverse ligament. Identify the pedicle, then the nerve exiting just caudal to the pedicle. The disc is caudal to the nerve.

Identify the cephalad transverse process.
  - Identify the pars interarticularis to stay medially.
  - The pedicle is the key landmark.
  - Laterally retract the intertransverse ligament.

CHAPTER 139

UPPER CERVICAL SPINE FRACtURES AND INSTABILITY

Claude Gelinas and Alan M. Levine

Introduction

Regional Anatomy

Classification, Pathology, and Treatment of Upper Cervical Spine Injuries

Chapter References

INTRODUCTION

Upper cervical spine fractures include a wide spectrum of injuries whose patterns differ from those of injuries in the lower cervical, thoracic, and lumbar spine because of the unique anatomic configuration of the vertebral elements of the craniocervical (45,57). The craniocervical includes the base of the skull, the atlas, and the axis, and is unique both in its bony as well as ligamentous structure. A variety of conditions can lead to upper cervical spine instability (infections, tumors, spondylosis, and congenital abnormalities), but the most common cause is direct trauma. Although upper cervical fractures occur as a result of mechanisms of injury that are similar to those causing other spine fractures (i.e., motor vehicle accidents, falls, diving, or direct trauma), they are nevertheless unique for several reasons. First, in autopsy series (2,13,17), many injuries to the upper cervical spine resulted in death to the brain stem and thus immediate death. In addition, in those patients surviving their initial trauma, the incidence of neurologic injury as a direct result of fractures and dislocations in the craniocervical is proportionately less than the incidence in other areas of the cervical spine because of the relatively large area available for the spinal cord within the spinal canal. Again, because of the unique relationship of this spinal region to the skull, most fractures in the upper cervical spine result from a force applied through the skull, with resultant excessive motion of the head and upper cervical spine, creating the injury pattern. Although the fractures in the upper cervical spine may be survivable, some of these patients succumb as a result of associated severe head injury. In fact, many of the neurologic deficit patterns are a result not of the injuries to the spine but of direct head injuries. To understand the nature of these injuries and to be able to apply the most appropriate treatment methodologies, the physician must first thoroughly appreciate the anatomic considerations of the craniocervical and then fully understand the mechanism associated with each injury pattern. Appreciation of the significance of the injury in relation to the immediate and subsequent patterns is important in preventing both undertreatment and overtreatment of injuries in this location. It also may alert the physician to potential pitfalls in treatment modalities that may apply to the various injury types.

REGIONAL ANATOMY

The term “craniocervical” is generally applied to the area at the base of the skull, the atlas, and the axis. The area is unique because it is the junction between the skull and the cervical spine, and is characterized by extreme mobility (37). It is unique also because of the size, shape, and location of the joints that allow motion between the occiput and the atlas or the atlas and the axis. At the lower end of the craniocervical (C2–C3), there is a transition in the size, shape, and location of the joints, transitioning to the more usual pattern seen in the lower cervical spine. Forces applied to the craniocervical may result in injuries having far different patterns and resultant instabilities than those seen in the lower cervical spine.

The occipitocervical articulations lie anterolaterally with reference to the spinal canal in that area. Those joints are made up of convex-shaped lateral masses adjacent to the foramen magnum that articulate with the concave lateral masses of the atlas. The joints are trapezoidally shaped and are somewhat wider medially than laterally. In children, these joints are less concave and flatter, and therefore, they restrict motion to a less significant degree than they do in adults. Therefore, children have more mobility and are more predisposed to injury at this level (3). The normal range of motion at the occipitocervical junction is 21° of extension (which is in part limited by the occiput abutting on the posterior arc of the atlas) (39), 3° of flexion, 7° of rotation, and 5° of lateral bending (64).

The atlas is unique in that it has no distinct body, an element present in the remainder of the vertebral column. Embryologically, the vertebral body of C-1 is absorbed into the formation of the dens process of C-2; therefore, the atlas has two lateral masses connected by an anterior and a posterior arch. The anterior arch is thicker and shorter than the posterior arch. The posterior arch has a tubercle in its posterior midportion and two relatively flatter areas just posterior to the lateral masses, where the vertebral artery runs after it exits from the foramen in C-2. The shape of the lateral masses is important because it helps one understand how injuries to C-1 occur. The articular surfaces for C1–C2 and also occiput–C1 are concave, with that of the atlantoaxial joint being somewhat flatter than that of the occipitocervical joint. The resultant shape of the C-1 lateral mass is that it is thinner medially than laterally; thus, when axial loading forces are applied across the craniocervical, there is a resultant force that serves to displace the lateral masses of C-1 in a lateral direction.

The axis is also unique in its relationship to the atlas because the atlantoaxial joint has two different sets of articulations. The first is the articulation of the slightly convex inferior articular process of the atlas with a slightly convex superior articular process of the axis. Both joints are oriented in the horizontal plane with a medial inclination of approximately 35°. These joints permit rotation, accounting for nearly 90% of the rotation in the cervical spine (69). The odontoid process projects up inside the ring of the axis, forming a second joint with the anterior arch of the atlas. The dens generally is between 14 and 15 mm in height and thus is approximately 40% of the overall height of the axis (73). The overall diameter of the atlas is quite large in relation to the space necessary for the spinal cord (62). Generally, the midsagittal diameter of the cord is one third of the midsagittal diameter of the inner surface of the axis. Actual rotation between the occiput and C-1 is generally approximately 5° to 7°, with more than 8° being pathologic, and at the atlantoaxial joint, the amount of normal rotation is approximately 43°, with more than 50° representing hypermobility and approximately 65° of rotation required for atlantoaxial dislocation (20,38). At C-2, the isolation of the pedicles of the axis between the atlantoaxial joint anterior to them and the C2–C3 joint posterior to them contributes to the occurrence of fractures at the base of the pedicles. The relative stability of the craniocervical as a unit isolates the pedicles of C-2, predisposing them to fractures. Finally, the large b idol process of C-2 is an anatomic landmark for physical examination as well as for anatomic dissection.

An understanding of the embryologic and postnatal development of the upper cervical spine is also helpful in further understanding injuries to this area. Although all other cervical vertebrae develop from at least three ossific nuclei, the atlas develops from only two centers of ossification, which usually fuse together between 3 and 5 years of age (60). Because there is an ossific center in each lateral mass, defects in both the anterior arch and posterior arch can occur. The axis has four centers of ossification, which also tend to fuse together between 3 and 6 years of age, with the exception of the junction between the odontoid process and the body, which may persist up to 11 years of age. The presence of persistent congenital defects in the ring of C-1 or C-2 in the adult and delayed fusion of ossific nuclei in children should not be confused with acute fractures.

The arterial supply to the dens initially comes from both the anterior and posterior ascending arteries from the vertebral arteries that anastomose to create a rich vascular network. The cartilage plate that separates the odontoid from the body of C-2, as previously mentioned, tends to ossify around 7 years of age, preventing direct vascularity from the rich plexus in the vascular body. There is also a zone of ossification at the tip of the dens, which appears between 3 and 6 years of age and can remain open until 12 years of age. Both of these delayed closures may be mistaken as fractures.

The relationship between the bony elements at each level of the craniocervical is far different from that between the bony components of the lower cervical spine. The major difference is that there is no disc between occiput and C-1 or between C-1 and C-2 because there is no vertebral body at C-1. Therefore, without the stability provided by the disc, the ligamentous integrity of the craniocervical is provided by a structure quite different from that in the lower cervical spine. The central point of ligamentous stability in the upper cervical spine is the odontoid process. Affixed to it are several ligaments, which provide resistance to translation, flexion, extension, and rotation. The transverse ligament is fixed at the tubercle on the lateral mass at one side of the atlas and traverses just posterior to the odontoid process to attach to the tubercle of the lateral mass. The transverse ligament provides stability in flexion between the atlas and the axis, and also prevents anterior translation of the atlas on the axis (29). The
The transverse ligament may become incompetent through two different mechanisms of injury. First, a severe flexion force between C-1 and C-2 may result in failure of the transverse ligament by impingement on the dens process, and this may also result in failure of the alar, apical, and accessory ligaments. In contrast, the transverse ligament can fail in tension with axial loading applied across C-1–C2, resulting in failure of the accessory ligaments and transverse ligaments, but because of the direction of attachment, the alar and apical ligaments retain intact. Additional stability to this complex is imparted by the joint capsules, especially the C1–C2 capsules (18). These capsules function to limit rotation and, to a lesser degree, translation at the C1–C2 level. Posterior to the central ligamentous complex is the pectoral ligament. This is an attenuation of the interspinous ligament, which is a direct restraint to flexion. The final ligamentous component in the upper cervical spine is the continuation of the anterior longitudinal ligament. This, again, is somewhat attenuated, although it provides restraint to extension in the upper cervical spine.

The final anatomic element with a critical role in treating injuries of the craniocervical junction is the vascular anatomy (56). There are three elements in the vascular anatomy of concern: the position and course of the vertebral arteries; the plexus of thin-walled vessels lying just posterior to the facet capsule at C1–C2; and the vascular supply surrounding the dens process. The vertebral arteries course upward through the foramen in C-2, then loop over the posterior arch of the atlas approximately 1.5 to 2 cm lateral to the tubercle of the posterior arch. The vertebral artery is vulnerable to injury during surgery in two separate areas. Dissection of the ring of C-1 more than 2 cm lateral from the midline may expose the vertebral artery to trauma. Also, the insertion of atlantoaxial screws exposes the vertebral artery to injury by direct trauma from a drill bit as it traverses the C-2 body. Because the location of the vertebral artery within C-2 varies, determine its position radiographically before screw fixation (53). It is, however, also important to know that because the vertebral arteries are paired structures (with one usually larger and, therefore, dominant over the other in terms of blood supply), injury to a single vertebral artery rarely results in significant neurologic deficit. In addition, as shown by Rauschning, there is a plexus of thin-walled vessels lying superficial to the facet capsule of C1–C2 with exposure of the C1–C2 articulation from a posterior direction. Sharp dissection through the soft tissue superficial to these vessels may result in profuse bleeding; there is less probability of injuring this vascular network by blunt dissection of the soft tissues caudal to rostral along the pedicle of C-2. Although the bleeding may be bothersome during the course of surgery, the consequences of disruption of the venous plexus is not significant.

Although it was originally thought that avascularity was the sole reason for the high rate of nonunion of the dens, it has since been found that in fact there is a significant endosteal and ligamentous blood supply (Fig. 139.2). The combination of the carotid arteries and vertebral arteries supply sufficient blood vessels to the dens process. Even the internal carotid supplies vessels to the dens through arteries that anastomose in a vascular arcade, and the dens may even have a direct blood supply through an ascending pharyngeal artery.

EVALUATION AND MANAGEMENT OF PATIENTS WITH INJURIES TO THE CRANIOCERVICAL

Although it is vital that any patient with potential trauma to the cervical spine be first assessed for adequacy of airway, breathing, and circulation according to the American Trauma Life Support (ATLS) protocols, it is even more vital in patients with injuries to the upper cervical spine. Especially with injuries caused by distraction at the level of occiput–C1 or C1–C2, brain stem contusion is possible, resulting in cessation of spontaneous respiration. Emergent maintenance of airway and respiration may be the key to patient survival. Treat any patient with a head injury who is comatose or obtunded as if an injury is present until it is clearly ruled out. As with other spinal injuries, immobilize the entire spine on a backboard with a rigid collar. The physical examination of patients with upper cervical spine injuries begins with an evaluation of the skull for evidence of head trauma, including scalp or facial lacerations. Localizing signs, such as tenderness and especially the location of trauma to the skull, is helpful in the further evaluation of the patient as well as ultimately determining the mechanism of injury. In the awake, alert patient, palpate the entire spine for areas of localized tenderness or asymmetry.

In the initial neurologic examination, test for muscle function and strength; evaluate sensation with pinprick and light-touch; check the deep tendon reflexes, cranial nerves, and rectal tone and perianal sensation. Physical findings help in ordering proper radiographic evaluation of the patient.

In upper cervical spine injuries, dense incomplete neurologic injuries are rare. The most common neurologic patterns are Brown–Sequard syndrome resulting from rotatory injuries at the occiput–C1 or C1–C2 areas, or flexion injuries with rupture of the transverse ligament. Brain stem injuries with impairment of respiration most commonly occur in occipital–cervical dissociations and often result in sudden death because of lack of respiratory effort. Radicular injuries (aside from injury to the spinal nerve, which can occur with fractures at C-1 resulting in numbness in the posterior aspect of the skull) are infrequent in the craniocervical junction. Because of the lack of a solid bony ring, incomplete spinal cord injury as seen in the lower cervical spine is uncommon. Neurologic deficit in patients with this type of injury is usually either severe or trivial. Fractures in patients without a neural deficit or with trivial deficits are usually diagnosed either on routine radiographic screening (especially in the elderly where pain may not be a significant component) or by the presence of pain in the upper cervical spine. Document the complete neurologic...
examination on a form such as the American Spinal Injury Association (ASIA) Neurologic Assessment form.

The initial radiographic series obtained by most surgeons includes a lateral cervical spine roentgenogram and may also include an anteroposterior (AP) roentgenogram, and for the upper cervical spine, an open mouth view. Correlate the findings on the initial roentgenograms of the upper cervical spine with the initial physical examination to determine whether additional radiographic workup is necessary.

**Radiographic Evaluation**

Radiographic evaluation of a patient suspected of having a spinal injury has two separate components. The first is to "clear" the cervical spine. The ultimate goal of this phase of evaluation is to ascertain as definitively as possible whether there is an injury in the cervical spine. The second phase is to define fully the nature of the spine injury once it has been shown to exist.

This evaluation ideally should be broken down into two separate approaches. In patients who are alert, oriented, nonintoxicated, and have no pain or neurologic symptoms, more than a single, lateral radiograph is unnecessary. The probability of finding significant injuries is very low in such patients. However, in patients with tenderness of the cervical spine or an altered state of consciousness, or in any polytrauma victim, perform a good quality lateral cervical spine film. An AP as well as an open mouth view may be indicated as part of the initial screening. It is clearly of no additional value to perform a five-view cervical spine radiograph (including two pillar views) unless you are trying to delineate a specific injury further. In patients with negative roentgenograms who are asymptomatic and have no neurologic deficit, obtain physician-supervised flexion-extension lateral views in an awake, alert patient to rule out ligamentous instability.

There is also considerable controversy concerning what should contribute final clearance of the cervical spine in an obtunded patient. The opinions range from keeping the patient immobilized until responsive enough to undergo further radiographic evaluation to performing multiple MRIs, obtaining an MRI scan to look for ligamentous disruption. If all radiographs are negative, we prefer to keep the patient immobilized until he or she is responsive enough to cooperate with further testing.

Assess the lateral radiograph in an organized way:

- Assess overall alignment.
- Evaluate each vertebral level (base of the skull, C-1, and C-2) for orientation. If one level is true lateral and the next is oblique, a rotatory abnormality can be inferred.
- Look for translation or kyphosis on the lateral view. Assess routine parameters such as the anterior spinal line, the posterior spinal line, and the spinolaminar line for continuity.
- Identify the line forming the base of the clivus (known as Wachenheim's line) to verify the appropriate gleno–occipital relationships. Draw a line along the posterior surface of the clivus and extend it inferiorly; it should intersect or lie tangentially to the posterior cortex of the odontoid.
- The distance between the tip of the clivus (basion) and the odontoid process, the basion–dental interval, should be less than 1.2 cm in adults.
- The Powers' ratio (71) is also useful in assessing possible occipital–cervical dissociation. This is the ratio of the distance of the basion and posterior arch of C-1 to the distance between the posterior margin of the foramen magnum (opisthion) and the anterior arch of C-1. A ratio greater than 1.0 is abnormal and further imaging with a computed tomography (CT) scan is indicated.

- The lateral roentgenogram also defines the atlanto–dens interval (ADI), which should be 3 mm or less in adults and 5 mm or less in children (32).
- Actual radiographic visualization of dens fractures may be difficult on the lateral roentgenogram. However, the angle of the dens with reference to the vertebral body of C-2 should be evaluated. Angles exceeding 20° should probably be considered abnormal or at least suggestive of a fracture and requiring additional evaluation.
- Fractures of the posterior arch of C-1 are generally visible on the lateral roentgenogram, but significant angulation of the posterior arch may be the only visible sign when the fracture line is in close proximity to the lateral mass of C-1.

Most types of traumatic spondylolisthesis in the axis can be visualized and fully defined on the plain lateral radiograph. Vertical distraction injuries at either occiput–C1 or at C1–C2 are easily visualized on the lateral radiograph and are most clearly defined on that study. Finally, the lateral roentgenogram can also be of some value in assessing the retropharyngeal soft-tissue shadow (68,85). The prevertebral soft tissue anterior to C-1 is clearly thicker than that more distal in the cervical spine. An increase in prevertebral soft-tissue shadow may not be present in the first hour or two of injury and is a quite unreliable sign in an uncooperative or screaming or crying patient. Soft-tissue shadows anterior to C-1 of greater than 10 mm in a cooperative patient suggest that there is some anterior column injury causing bleeding into the retropharyngeal space. This finding, in combination with a posterior arch fracture at C-1, would suggest that there is an anterior element injury as well.

The final critical element in evaluating lateral films is to look for contiguous or noncontiguous injuries in the cervical spine (65). Injuries in combination usually have the same mechanism of injury. The initial lateral roentgenogram may reveal an associated injury in 22% to 50% of patients, depending on the pattern and severity of the upper cervical injury.

The AP view contributes relatively less to the evaluation of the upper cervical spine than it does to the evaluation of the lower cervical spine. However, the posterior elements of C-1 and C-2 can be visualized with this view. One of the more critical features is to assess the orientation of the spinous processes. Loss of alignment of the spinous processes is highly suggestive of a rotatory injury in the upper cervical spine. In addition, an angular deformity on the AP roentgenogram may also be helpful, especially in patients with torticollis, for whom the lateral may be extremely difficult to assess. The AP is also helpful for assessing concurrent injuries in the lower cervical spine.

A well-oriented open mouth view defines the occipital condyles, may show evidence of a fracture of the occipital condyles, and also gives an excellent view of the lateral masses of C-1. Spreading of the lateral masses of C-1 is indicative of a fracture of the anterior arch of C-1, as seen in Jefferson's fractures. The total displacement of the lateral masses can be evaluated (86), providing an indication of rupture of the transverse ligament. The radiographic appearance of a rotary subluxation at C1–C2 is often defined on the open mouth radiograph with the so-called "wink" sign (overlapping of the inferior edge of the lateral mass of C-1 and the superior edge of the lateral mass of C-2, thus apparently eliminating the joint space (83)). The odontoid–lateral mass relationship (distance from lateral mass to dens on each side), which sometimes is cited as a pathologic sign, is, in fact, asymmetric in many normal individuals and is of little significance (52,67).

The primary use of CT scans is to enhance the anatomic delineation of fractures that have already been identified. Make the slices at a 1.5 or 2 mm interval to enhance coronal and sagittal reconstructions and three-dimensional reconstructions. In fractures of the atlas, the gantry of the CT scanner must be parallel to the arch of C-1. If care is not taken with the orientation, the views will be difficult to interpret and not add much information to the plain radiographs. At C-1, the CT scan is most helpful in defining the nature of injuries involving the ring. For injuries of the transverse ligament, CT scanning is of help where the disruption of the transverse ligament is with a bony avulsion. In those dens fractures in which the fracture line is not clearly visualized on either the AP or the lateral plain radiographs, but an angular deformity of the dens is noticed, a CT scan with midsagittal reconstructions may define the injury. CT scanning is also helpful for defining dens anatomy before screw fixation (44). It is excellent in defining abnormal C1–C2 relationships, especially in rotatory dislocations and subluxations (21,60,61,83), and as defined by Sonntag and Dickman (79), the CT scan with appropriate reconstruction may also help define the position of the vertebral artery and determine whether placement of an atlantoaxial screw is possible.
EMERGENT IMMOBILIZATION OF THE UPPER CERVICAL SPINE

Patients who have sustained high-velocity vehicular injury, or those who are suspected of having a spine injury, will usually present to the emergency facility immobilized in a collar and on a spine board. Continue this immobilization until the spine has been cleared or until definitive immobilization and treatment can be instituted. Most cervical spine injuries in patients without neurologic deficit can be cervical spine injuries in a collar until evaluation by CT scan and MRI is completed. Thus, a neurologically intact patient with a posterior arch fracture who is suspected of having a Jefferson fracture may undergo a CT scan using collar immobilization. In contrast, some place patients with transverse ligament rupture and a Brown-Séquard lesion in traction immobilization before initiating any further radiologic evaluation to keep the patient immobilized in a Philadelphia collar and not to convert the patient to traction until the workup is completed. This makes transfer into the imaging machinery easier. With transfer in and out of a CT scanner or MRI machine, any traction will generally need to be discontinued several times, with some additional risk to the patient. Furthermore, it is critical with certain injuries, such as traction injuries to the upper cervical spine, that traction not be applied at all. If this mechanism is not recognized, even traction weights as small as 10 lb can cause stretching of the brain stem or cord with additional neurologic injury.

Next, decide what type of traction immobilization to apply once the radiologic examination is completed. The decision depends on two factors: What personnel are available to apply the traction device? What is the goal of applying the device to the patient? It is far simpler and more expeditious in the emergency setting to place Gardner–Wells tongs, because this procedure can be done accurately by one person in a very short period of time and with minimal movement of the patient. Placement of a halo ring requires precise positioning of the patient and a surgeon and an assistant to make sure that the ring is applied properly. If the goal is simply to apply a traction force to either reduce or stabilize an injury before surgery, in which the surgical procedure will give definitive stabilization not requiring postoperative immobilization in a halo vest, Gardner–Wells long traction is preferred. In contrast, in injuries that require initial reduction by traction and that will either be treated definitively in a halo vest or treated by surgery most likely will require additional postoperative immobilization in a halo vest, initial placement of a halo is appropriate. A third group of patients—those with distraction injuries to the cervical spine, such as occiput–C1 dissociations or type IIA traumatic spondylolisthesis of the axis—will be placed in a halo and then immediately in a halo vest for stabilization. No traction is indicated in either of those injuries but ensuring stability is important.

Decide whether the halo can be placed with the patient in a supine position or whether the erect position is safe, which simplifies the placement. Patients with grossly unstable injuries or multiple injuries cannot tolerate a sitting position, and thus require application in the supine position using a head-positioning apparatus and an open ring halo to allow accurate placement. In those patients who have an isolated upper cervical spine injury, such as a minimally displaced dens fracture, the halo ring can be applied by using a cervical collar and placing the patient in the sitting position, for placement of the ring and, subsequently, the vest.

Application of Skull Tong Traction

Apply cervical tongs, such as Gardner–Wells tongs, in the supine position. Cleanse the hair directly above the external auditory meatus of the ear with povidone-iodine (Betadine) solution, but shaving the patient’s hair is not necessary.

Place the tongs through the ring and insert at a site directly superior to the external auditory meatus and one fingerbreadth above the pinna. Before application of the tong, inject the area down to the periosteum of the skull with 1% lidocaine, usually with epinephrine (1:100,000).

Do not incise the skin. Tighten the pins simultaneously and, depending on the manufacturer’s recommendations, bring the pressure indicators either to the level of outer surface of the pin or approximately 1 mm beyond.

The initial traction weight in an adult is generally 10 lb, but before adding any weight, ascertain that the injury will not be made worse by traction.

Increase the weights incrementally and obtain an appropriate radiograph between each increase to ensure that overdistraction is not occurring.

Although the general formula of 5 lb (2.3 kg) per cervical level above the fracture, with an initial 10 (4.6 kg) to 15 lb (6.8 kg) to overcome the friction of the head on the bed has been suggested, this is often not enough to reduce certain cervical spine injuries. The weight in certain types of traumatic spondylolisthesis as well as Jefferson fractures will need to be increased to as much as 30 lb (13.6 kg) before an acute injury can be reduced. Between each 5 lb (2.3 kg) increment, however, appropriate radiographic evaluation is critical.

Application of a Halo Vest

Placement of a halo and subsequently a halo vest is more difficult and requires at least two people.

Before placing the ring, measure the head and torso and size for the halo and vest according to the manufacturer’s instructions.

Place the patient in the supine position or an operating table and use either a mechanical head holder or positioner, or apply the halo with the patient in the sitting position.

Select the pin sites carefully; four pin sites are adequate in the adult, but more may be needed in the elderly patient with a thin skull or in the child.

The preferred sites for halo insertion have been determined by a series of radiographic, cadaver, and clinical studies. Anteriorly place the pins approximately 1 cm superior to the orbital ridge, below the equator of the skull, and over the lateral two-thirds of the orbit. This will generally avoid the temporalis muscle, the supra-orbital branch of the trochlear nerve, and the frontal sinuses. (Fig 139.4)

Figure 139.4. The “safe zone” for placement of halo fixator pins. Place the anterior pins anterolaterally, approximately 1 cm above the orbital rim, below the equator of the skull, and cephalad to the lateral two thirds of the orbit. The safe zone avoids the temporalis muscle and fossa laterally, and avoids the supracrural and supratrochlear nerves and the frontal sinu mus. (Redrawn from Baltuck RT, Botte MJ, Garfin SR. Complications of Halo Immobilization. In: Garfin SR, ed. Complications of Spine Surgery. Baltimore: Williams & Wilkins, 1989, with permission.)

- Place the pins so that the pins are as far laterally as possible to minimize prominent scarring. Avoid placement within the temporalis muscle and fossa because it is particularly painful with motion and could cause significant bleeding; in addition, the area has a very thin cortical base, making perforation more common.
- The posterior sites are less critical and are generally placed at 180° on the contralateral side. Any area 2 to 3 cm posterior to the edge of the pinna of the ear is generally satisfactory. Shave the areas so that hair is not trapped as the pin is placed.
- Prepare and anesthetize each pin site by passing the needle for the local anesthetic through the selected hole or from above the halo to the exact contact point on the skin and deep tissues down to the skull.
- Ask the patient to close his or her eyes, and then make a small vertical incision with a #11 blade, directly in line with the selected screw holes. Some surgeons place the pins without using skin incisions. Place the four pins through the halo and screw them into the small incisions. Tighten the pins in a sequential manner so that the fracture is reduced by overcoming one side before bothering the other.
- Tighten the pins in 2-inch-pound increments to a maximum of 8 inch-pounds in the normal adult skull. Tighten to lower levels when multiple pins are used in either the child or the osteoporotic elderly adult. Although 6 inch-pounds were initially used, 8 inch-pounds appears to have a lower rate of complications in terms of loosening and infection.
- Once the optimal torque is achieved with a torque screwdriver or a disposable wrench, place lock nuts over the pins and tighten them to prevent backing out of the pins.
- Apply traction through the halo ring using a bale, or the halo can now be connected to a vest. After applying a halo vest in the supine position, mobilize the patient to an upright position and recheck the halo vest.
- Now check the reduction of the cervical spine with a radiograph with the patient supine, if applied in the supine position, and then obtain a second radiograph in
the upright position to be certain that the reduction does not shift. Obtain another upright roentgenogram 24 hours after the patient is allowed to ambulate, to ensure the maintenance of position. Subsequent adjustments to the halo, in terms of position of the fracture, should be done in the upright position for optimal vest fit.

With a torque wrench, retighten all four pins in the halo at 24 hours back to 8 inch-pounds. Teach the patient to cleanse the pin sites daily and to inspect for any problems.

**CLASSIFICATION, PATHOLOGY, AND TREATMENT OF UPPER CERVICAL SPINE INJURIES**

Bony and ligamentous injuries can be classified in a number of different ways, although it is probably easiest to classify them by level as opposed to any type of mechanistic classification (Table 139.1).

<tr>
<td>Injuries involving the occipital–cervical junction are extremely rare and often are fatal. This group of injuries includes dislocations that can occur with or without occipital condyle fractures, as well as occipital condyle fractures that occur without any subluxation. In addition, there are pure distraction injuries at the occipital–cervical junction. These are the most commonly fatal. These injuries may be overlooked in the acute emergency because they are uncommon and difficult to diagnose on plain roentgenograms. Many of these injuries are found only at autopsy (3). The injuries are commonly associated with other noncontiguous cervical spine fractures and with head injuries. The presence of a high-level neurologic deficit, often with involvement of all four extremities plus abnormal respiratory function, known as “pentalgia,” is a tilt to injury at the occipital–cervical junction. As a group, these injuries most commonly result from high-speed motor vehicle accidents or are found in pedestrians struck by motor vehicles (4,5,13,56,73,86). The cause of death may be due to the associated head injury or sudden loss of voluntary respiratory function because of brain stem injury from the occipital–cervical dissociation (53).</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Patients with isolated occipital condyle fractures have a higher rate of survival than occipital–cervical dissociations or dislocations. Patients may present with cranial nerve involvement as well as persistent occipital headaches. The mechanism of injury of all occipital condylar fractures is believed to be either sudden deceleration or direct axial loading on the cranium. Occipital–cervical dislocations can occur as a result of violent hyperextension or distraction forces in which the torso is pinned in position and the distraction force applied to the neck by a force applied beneath the patient’s chin. Occipital condyle fractures have been characterized by Anderson and Montesano (4) (Fig. 139.5). A type I fracture (Fig. 139.5A) is an unilateral undisplaced, comminuted fracture of the condyle, usually resulting from axial impact between the skull and the axis. The alar ligament may be disrupted on that side, but the segment is usually stable. A type II fracture (Fig. 139.5B) is an unilateral occipital condyle fracture that is associated with a basilar skull fracture on the same side. The mechanism is generally axial loading with lateral bending, and this injury is generally stable. Type I and II injuries can be treated nonoperatively using a rigid cervical orthosis for 6 to 8 weeks; halo mobilization is not generally required. The type III fracture (Fig. 139.5C) is an unilateral alar ligament avulsion from the occipital condyle. It occurs as a result of extreme lateral bending, rotation, or a combination of the two. This injury, because it has a ligamentous component, may be associated with atlanto-occipital dislocations. Type III fractures may be unstable. Treatment is based on the degree of instability, ranging from collar immobilization, to halo immobilization, to posterior occipital–cervical fusion if associated disruption of the occiput–C1 complex is significant. Perform flexion-extension radiographs at the end of nonoperative management to assess the degree of stability. At that point, abnormal motion can be considered evidence of either nonunion or nonhealing of the ligamentous injuries, which requires treatment with an occipital–cervical fusion. Occipital condyle injuries are commonly unilateral but may be bilateral as well.</td>

<tr>
<td>Occipital–cervical subluxations and dislocations have been incorporated into a single classification described by Traynelis et al. (68) (Fig. 139.6). Type I injuries are anterior dislocations and generally have the highest survivability. Type II injuries demonstrate vertical displacement, usually from a distraction mechanism: type IIa injuries occur at the occipital–cervical junction, and type IIb injuries occur between the atlas and axis. In some cases, these injuries may be combined injuries. When there is greater than 2 mm of vertical displacement between the occiput and C-1 (IIa), a rupture of the tentorial ligament and alar ligaments must be suspected. At the C1–C2 level (IIb), the joint capsule is usually involved as well as the tentorial membrane and the alar ligaments. Injuries to the transverse ligament can also occur. Type II injuries should not be placed in longitudinal traction. Type III injuries are posterior dislocations and are often fatal, although accompanying fracture of the C-1 arch may increase the chance of survival. Types I and III injuries may be realigned initially using traction, although the degree of ligamentous disruption is difficult to assess initially. Traction should be used only in type I and type III injuries, with traction restricted to between 2 (0.9 kg) and 5 lb (2.3 kg). Interestingly, gravity itself is usually sufficient to reduce any translation. Increased survival has been reported with traction (26). After closed reduction is achieved, immediately place the patient in a halo vest and obtain a CT scan to identify any fractures. After this assessment, treat only patients with minimal ligamentous destruction and minimal bony disruption definitively in a halo vest for a period of 3 months. At the conclusion of that time, perform flexion-extension roentgenograms to check stability and decide whether a occipital–cervical fusion is necessary based on the degree of residual translation.</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
The advantage of occipital–cervical fusion with two plates and screws is that there is no need for halo immobilization.

- With the patient in the traction applied at the time of admission, perform an awake fiberoptic intubation. Then turn the patient into the prone position while still awake.
- Use a three-pin Mayfield (Ohio Medical Instrument Co., Inc., Cincinnati, OH) or halo modified headrest to secure the head. Induce general anesthesia once appropriate positioning is obtained and the patient's neurologic status is reassessed and found to be unchanged.
- Any manipulation of the head is done before inducing general anesthesia. Avoid extreme positions of flexion or extension because the plate fixation is rigid.
- Set up fluoroscopy so that AP and lateral images can be easily obtained, preferably simultaneously with two machines.
- Before incision, hold a guidewire alongside the neck and visualize it on a fluoroscope to be sure that the C1–C2 transarticular screw can be placed with the patient as positioned. This technique generally cannot be accomplished in patients with an upper thoracic kyphosis or gibbous.
- Make a posterior incision from the occipital prominence and extend it to the midcervical spine. Elevate all soft tissue off the bone from the greater occipital prominence to the C2–C3 joint.
- Select two plates with appropriate hole spacing and then contour them to fill the occipital–cervical junction, with at least three fixation holes available in the occiput and extending far enough distally to allow a C1–C2 transarticular screw to be placed on each side.
- Take care in contouring the occipital portion of the plates so that the terminal end is not prominent and the screw fixation is on the undersurface of the occiput rather than on its most prominent posterior portion.

Then place the occipital screws using three bicortical screws per side. The screws are typically between 6 and 12 mm in length. In older patients, the dura may be adherent to the inner surface of the skull, causing a small cerebrospinal fluid (CSF) leak, but this can be easily stopped by simply placing the screw in the hole.

- Then apply the second plate in a similar fashion.
- Fashion a corticocancellous graft to lie between the two plates, covering the posterior portion of the occiput, the posterior arch of C-1, and around the spinous process of C-2. Hold this graft in place using heavy suture or wire.
- If transarticular screw fixation cannot be achieved because of the patient's position, alternatively, a C-2 pedicle screw can be placed, generally in combination with a C-3 lateral mass screw and a wire or suture placed around the arch of C-1 and tied to the plate on either side.

Immobilize the patient postoperatively in a rigid collar for 12 weeks. While the patient is in the collar, be certain that he does not develop an occipital decubitus either because of the cervical spine trauma resulting in anesthesia in the area of the greater occipital nerve or as a result of the surgical dissection.

Posterior Occipital Fusion

In most cases, however, these are extremely unstable injuries and a posterior occipital–cervical fusion is indicated. Various techniques have been used to achieve an occipital–cervical fusion. The most rigid fixation involves the use of a contoured plate secured with multiple occipital screws and a C1–C2 transarticular screw (24,38,39) (Fig. 139.7). Techniques for occipital–cervical wiring, described by Wertheim and Bohlman (60), require postoperative immobilization in a halo vest, but in their series, all 13 patients developed a solid arthrodesis. Other techniques using corticocancellous struts wired into the skull and C1–C2 transarticular screw (24,38,39) have been used to achieve an occipital–cervical fusion. Almost 50% of fractures involving the atlas are associated with a second fracture, and approximately 25% of them are associated with noncontiguous second fractures. The two most common types of fractures associated with a fracture of the atlas are fractures of the dens (27.55.56) or type I traumatic spondylolisthesis (55). Because the majority of injury patterns for fractures of the atlas involve widening of the space available for the cord rather than narrowing of the canal area, these injuries are not generally associated with neurologic deficit. If a deficit is present, its etiology may be from another associated or nonassociated spine or head injury. Multiple types of fractures of the C-1 arch have been identified (Fig. 139.8). The initial description of fractures of the C-1 arch was by Jefferson (48,49). He described isolated fractures of the posterior arch as well as multiple fractures of the arch, although his name is most associated with the four-part fracture. Sebag et al. (77) have actually identified six different fracture patterns. However, the most common injury type is the posterior arch fracture. This is thought to be the result of a hyperextension-axial loading injury in which the posterior arch is pinched off by the occiput and the ring of C-2 (92). These fractures tend to occur at the area just behind the lateral mass where the vertebral artery passes over it. Associated with this hyperextension-axial load mechanism of injury are other fractures that have a similar mechanism, such as posteriorly displaced dens fractures, type I traumatic spondylolisthesis of the axis, and C-2 posterior extension teardrop fractures.

**Figure 139.8.** Four major types of fractures can occur at the level of the atlas. Type I is the most common and is a posterior arch fracture, which is the result of hyperextension and axial loading. It may be associated with other injuries caused by the same mechanism, such as traumatic spondylolisthesis. Type II, or lateral mass fracture, is the result of axial loading and lateral bending. There is usually a fracture line anterior and posterior to the lateral mass, causing asymmetric spreading. A second fracture line can also be present in the contralateral posterior arch. Type III, or Jefferson's fracture, is a burst fracture resulting from axial loading of C-1. Two to five fracture lines can be present, although most commonly there are four fracture lines: two in the anterior arch and two in the posterior arch. The final category, type IV, is an avulsion fracture of the anterior tubercle of the atlas. (From Levine AM, Eismont FJ, Garfin SR, Zigler JE. Spine Trauma. Philadelphia: W. B. Saunders Co., 1998, with permission.)

The second most common type of injury, the lateral mass fracture, is generally composed of a fracture anterior to the lateral mass and one posterior to the lateral mass. In some instances, there may also be a fracture through the posterior arch on the contralateral side (42-55). These fractures have the same degree of instability, whether they are two-part or three-part injuries. The mechanism of injury is an axial load with lateral bending. The presence of a second fracture on the contralateral side would suggest at least some slight extension associated with this injury. In addition, the most common fracture occurring in association with this type is a lateral mass fracture in the lower cervical spine, which also has the same mechanism of extension, axial loading, and lateral bending.

The third type of fracture is what has been called the Jefferson fracture, which is a classic bursting injury of the ring of C-1. It has variably been described as having two fractures, one in the anterior arch and one in the posterior arch; or having three fractures, one in the anterior arch and two in the posterior arches; or having four or five fractures, with at least two in the anterior arch and two in the posterior arch. On open mouth radiograph view, this generally shows symmetric displacements of the lateral masses of C-1 (43,48,49,56,77). The injury is believed to be the result of axial loading applied to the skull. Because the lateral masses of C-1 are wider laterally than medially, they act like a wedge when they are axially loaded, driving the lateral masses laterally and disrupting the ring. Splaying of the lateral masses more than 6.9 mm on an open mouth view may indicate disruption of the transverse ligament (60).

The fourth type of fracture is an avulsion fracture off the inferior portion of the anterior tubercle of C-1, where the longest colli muscle inserts. It is generally the result of hyperextension and, therefore, is an avulsion injury. It is completely stable (63). The final type of injury is a transverse process fracture, which may be either unilateral or bilateral (15).

In general, isolated posterior arch fractures can be treated nonoperatively with 6 to 12 weeks of immobilization in a hard collar. Nonunion is exceedingly rare (55,77). Patients who have a dens fracture in association with a posterior arch fracture cannot be stabilized by standard C1-C2 wiring techniques. Without the integrity of the posterior arch, either an anterior dens screw or a posterior transarticular C-1 atlantoaxial arthrodesis may be necessary when operative treatment is indicated. Avulsions from the anterior tubercle and transverse process fractures can be treated symptomatically with simple collar immobilization until pain relief is achieved.

Lateral mass and Jefferson's fractures can be divided into two groups: those that are only minimally to moderately displaced (less than 7 mm total displacement on an open mouth view) and those that are more significantly displaced. Controversy remains concerning the most effective treatment for these injuries. For minimally to moderately displaced fractures, the transverse ligament is intact. Immobilization in a hard collar for less significantly displaced injuries or immobilization in a halo vest for more significantly displaced injuries appears to give adequate long-term results. The most common complications of treating these patients is symptomatic nonunion (77) in those patients who have displaced fragments of the ring that do not unite. If the fragments are symptomatic, they may require arthrodesis. Remember that the halo and vest cannot be expected to reduce the ring fragments, even with traction. Once traction is removed, the original displacement will recur. Thus, placing the patient in traction for several days before immobilizing the patient in a halo vest does not improve the degree of displacement (42,94).

Patients who have had rupture of the transverse ligament and, therefore, more than 7 mm displacement on an open mouth radiographic view can be treated in one of two ways. Although it was initially thought that these patients would have long-term instability without surgical intervention, on the basis of the apparent rupture of the transverse ligament (75), this has turned out not to be the case (51). Thus, if the patient can achieve union of the ring of C-1, the degree of instability, after treatment, is limited. As demonstrated earlier by Fielding (22), this is because only the transverse ligament is ruptured, and the alar, apical, and accessory ligaments as well as the joint capsule are still intact and providing sufficient stability. Thus, the degree of C1-C2 instability is minimal when the ring heals solidly (55). Therefore, patients can be treated with enough longitudinal traction to reduce the splaying of the lateral masses to anatomic position and then held in longitudinal traction until early healing takes place (approximately 6 weeks). Once preliminary healing has occurred, the patient can be mobilized in a halo vest for an additional 6 weeks without risk of loss of reduction.

If, however, the reduction is achieved initially and then the patient is immediately mobilized (within the first week), reduction will be lost. Because of the long hypertrophic reaction required, long-term traction is less popular than it was previously. In addition, if the patient cannot be left in a supine position on a Stryker (Stryker Corp., Kalamazoo, MI) frame for long periods of time, operative treatment for significantly displaced fractures may be indicated.

In that case, reduce the ring with axial traction and then perform a C1-C2 transarticular screw fixation (63).

**Posterior C1–C2 Arthrodesis, Modified Magerl Technique** The treatment of a widely displaced lateral mass or Jefferson's fracture is the modified Magerl transarticular C1-C2 screw fixation. The technique, however, has to be modified over that originally described by Magerl and Seemann (Fig. 139.9) (65) because a considerable portion of the stability of the technique is with the bone block that is usually placed between the intact posterior arch of C-1 and the spinous process of C-2. Because a Jefferson's fracture has an incompetent C-1 arch, additional stress is placed on the screws, risking early failure of fixation. Therefore, denude the cartilage of the facet joints, and pack bone directly into the posterior aspect of the C1–C2 joint. Also, place graft between the ring of C-1 and C-2, recognizing, however, that its structural integrity is compromised. Postoperatively, additional immobilization may be necessary in the form of a rigid collar or a halo vest, depending on the original degree of instability, the quality of the patient's bone, and the quality of the fixation.
Figure 139.9. An alternative method for the treatment of a widely displaced lateral mass or Jefferson's fracture is the Magerl transarticular C1–C2 screw fixation. See text for details.

- Reduce the fracture with halo traction using about 30 to 35 lb (13.6 to 15.9 kg) of traction to achieve an anatomic reduction, which makes placement of the screws relatively straightforward. Further reduction is not possible once operative stabilization has begun. Use a biplanar fluoroscope imaging.
- The only variation in the standard technique is that the joints are fully exposed (Fig. 139.9A) so that the cartilage can be curetted out for fusion, and no fixation of bone graft is possible between the fractured arch of C-1 and the lamina of C-2.
- Graft directly into the facet joints and also do an onlay graft from C-1 to C-2 (Fig. 139.9B) so that as healing occurs, a solid arthrodesis will also occur. With satisfactory screw fixation, either the halo vest can be continued postoperatively or hard collar can be used.

In patients treated with arthrodesis who attain a satisfactory fusion, long-term results in terms of stability are excellent. In patients with relatively undisplaced lateral mass fractures and Jefferson's fractures treated only in a collar or halo vest, late instability is rare if union is achieved between all fragments (55,77). The motion between C-1–C2 however rarely returns to normal. In the Levine and Edwards series (55), up to 80% of patients had some residual neck pain, although none required secondary fusions for neck pain (55). The significant joint incongruity and resultant degenerative changes in fractures that are significantly displaced at the conclusion of treatment will commonly lead to pain and secondary occipital cervical fusion. In one study, nonunions occurred in 17% of patients (77), and nonunion was directly related to the amount of displacement. Patients with a nonunion and displacement of the posterior arch could sustain neural compression on the basis of the displaced fragment, but this is a rare complication.

### Atlantoaxial Instability (C1–C2 Injuries)

Atlantoaxial instability may occur secondary to trauma, congenital abnormalities, infection, and arthritis. Traumatic atlantoaxial instability can be of two types. It can be related to flexion instability with anterior translation of the atlas on the axis resulting from rupture of the transverse ligament and disruption of the secondary stabilizers—the alar, apical, and accessory ligaments. The second type of atlantoaxial instability is a rotatory instability, which can be of several different types and be the result of both bony and ligamentous injuries. The transverse ligament is the primary stabilizer, preventing anterior translation of C-1 on C-2, but the alar, apical, and accessory ligaments, as well as the capsular ligaments, offer secondary stabilization. Posterior translation of C-1 on C-2 is prevented by the impingement of the anterior ring of C-1 on the dens. As shown by early work by Fielding et al. (29), a maximum of 3 mm of anterior translation of C-1 on C-2 can occur with an intact transverse ligament in the adult. Within the range of 3 to 5 mm of translation, catastrophic failure occurs, usually within the midsubstance of the ligament rather than at the bony attachments. No correlation has been made between the strength of the transverse ligament and age other than that children tend to be slightly more lax and, therefore, an ADI of 5 mm of translation can be accepted in children as normal. Simple experimental sectioning of the transverse ligament without disruption of the alar, apical, and accessory ligaments results in an ADI of only 5 mm in the adult in the experimental setting (29). In patients with gross instability with an ADI greater than 10 mm, not only does the transverse ligament need to be sectioned but all of the secondary restraints as well.

Most of these injuries are the result of significant trauma to the head, although they may occur in older patients with a simple fall and striking of the occiput. Patients may have varying neurologic involvement, from being neurologically normal with severe neck pain to a transient quadriparesis to a Brown–Séquard–type syndrome. The diagnosis of this injury is generally made on a lateral roentgenogram. If roentgenograms are taken in the supine position, the subluxation may reduce, especially in a patient whose chest is disproportionately large in relation to his or her head, thus placing the patient in extension, as is frequently the case with children. If the patient does not have neurologic deficit and injury is suspected, physician-supervised flexion-extension films in the alert, awake, neurologically intact, cooperative patient may be very helpful in making the diagnosis. In contrast, if the patient has severe neck pain and paraspinal muscle spasms, adequate-quality flexion-extension films may not be attainable. There may not be enough motion in the cervical spine to indicate whether the patient has instability. In that case, several options are available. The patient may be simply immobilized in a hard collar, and when the spasm subsides, adequate flexion-extension films can be obtained. Alternatively, under physician supervision, the amount of spasm in the paraspinal musculature can be reduced by intramuscular injection, allowing flexion-extension roentgenograms to be taken. An MRI may be used to investigate the integrity of the ligamentous complex.

Healing of the transverse ligament, even in the case in which its insufficiency is the result of the avulsion from its insertion on the lateral mass of C-2, is uncommon. This is one of the few injuries in the upper cervical spine that routinely requires surgical intervention. There are a variety of techniques to achieve C1–C2 arthrodesis. These are commonly done by posterior arthrodesis because it is infrequent to have a fracture of the posterior arch and a rupture of the transverse ligament from a flexion type injury. C1–C2 fusion, using either a Galilé (35), Brooks (12), or a Magerl (48) C1–C2 transarticular screw fixation, will give satisfactory results in this situation.

Until recently, the most common method for surgical stabilization for C1–C2 was either a Galilé or a Brooks (12) fusion (Fig. 139.10). With any method, significant loss of rotation at the atlantoaxial joint will occur postoperatively because 50% of neck rotation normally occurs at this joint. In fact, because of compensatory motion at other joints, the loss is often less, as reported by Fielding et al. (30). Fielding demonstrated that an average loss of only 13% of rotational motion occurred in patients younger than 20 years of age, a 25% loss occurred in those in the 20- to 40-year-old age group, and a 26% loss occurred in those older than 40 years of age.

Modified Brooks Fusion In both the Brooks' and Galilé's techniques, wires are passed beneath the arch of C-1, around the spinous process of C-2 in the Galilé technique and sublaminarily beneath the arch of C-2 in the Brooks technique. With the Galilé technique, a corticocancellous bone block is laid on the arch of C-1 and notched to fit around the spinous process of C-2. There are a number of different modifications of the Brooks technique, ranging from two wedge-shaped blocks (Fig. 139.10), one on each side, with a single wire around them, to two wires around them, to instances of a single block in the center with wires that pass beneath the lamina at C-1 as well as sublaminar at C-2.

![Figure 139.10](image-url)
On both the right and left, pass sutures under the posterior arch of the atlas (Fig. 139.10A). Then pass the sutures on the lamina of C-2. A twisted wire is then tied to the suture, which is used to guide the wire under the arch of the atlas and the lamina of the atlas (Fig. 139.10B). In the Figure 139.10C the wires are now in place and lie anterior to the anterior portion of the atlantoaxial membrane, which was not removed during exposure of the posterior elements of the atlas and axis.

Harvest either two iliac crest corticocancellous grafts or one larger midline graft and fashion them to fit between the posterior arches of C-1 and C-2. Bevel edges to fit in the interval between the atlas and axis. Hold the graft in place with a towel clip. When they are wired in place, the beveled edges will be in contact with the arch of the atlas and the lamina of the axis.

Secure the graft or grafts with the wires (Fig. 139.10D).

Several congenital anomalies are associated with atlantoaxial instability. These include Down’s, Morquio’s, and Klippel–Feil syndromes, as well as occipitalization of the atlas. The incidence of atlantoaxial instability in Down’s patients has been reported to be as high as 20%. There is still controversy surrounding the need for prophylactic fusion in these individuals. Most recommend restriction of contact activities in patients with an ADI of less than 7 mm. Prophylactic fusion is recommended for displacement of greater than 7 mm.

### Atlantoaxial Rotatory Deformities

Atlantoaxial rotatory deformities have a number of different etiologies including trauma, tumors, and inflammatory conditions (31,64,93). They have been classified anatomically by degree of subluxation (31) and clinically by the duration of symptoms, response to treatment, or their underlying etiology. They are most commonly due to infection or trauma and have been reported in all age groups, with a higher incidence in children (70) and young adults, regardless of the etiology. The typical presentation for infection is a sudden onset of torticollis in which the head is rotated away and tilted anteriorly toward the rotated side with associated spasm of the sternocleidomastoid muscle. The patients generally have significant neck pain and an inability to rotate the head past neutral. By palpating the posterior wall of the occiput, it is possible to feel the difference between the normal and abnormally rotated lateral masses. On the subluxed side, it is possible to appreciate a stepoff from the C-1 lateral mass to the C-2 lateral mass. Any motion produces significant discomfort. In long-standing cases, facial asymmetries may occur. Compensation for the torticollis may occur after some time as a result of counterrotation in the lower cervical spine or atlanto-occipital joint.

The most characteristic finding on the lateral radiograph is an obliquity in the orientation of the posterior arch of C-1 in comparison to the remaining lower spinous processes. A widened ADI may be seen. On the open mouth view, the anteriorly rotated lateral mass can appear wider and closer to the midline than the opposite side. However, the most pathognomonic sign on the open mouth view is the “wink” sign when the inferior edge of the lateral mass of C-1 on the affected side overlaps the lateral mass of C-2, obliterating the joint space. On an AP view the spinous process of C-2 may be rotated away from the side of the anterior displaced lateral mass, known as Sudeck’s sign (84). A fixed subluxation can be easily seen on a thin-cut CT scan, which demonstrates the abnormal relationship of C-1 to C-2 (21,33,63). The dimensional reconstructions are also very useful for complete delineation of the injury. For reducible subluxations, a dynamic CT scan in maximal left and right rotation will generally reveal the deformity.

The classification is based on the integrity of the transverse ligament and the direction of the deformity (7,31). A type I deformity indicates an intact transverse ligament and a fixed C1–C2 position within a normal range of rotation. Type II deformities show mild deficiency of the transverse ligament with an ADI of 3 to 5 mm. Mild fixed rotation exceeds the normal range of the C1–C2 joint. A type III deformity has an ADI greater than 5 mm, and both lateral masses of C-1 are displaced anteriorly, with one side rotated farther than the other. A type IV deformity describes a posterior subluxation of one or both lateral masses. Types III and IV have greater instability with increased neurologic risk, and decreased success with conservative management. Posttraumatic episodes of atlantoaxial deformity have a higher rate of instability and require more aggressive treatment. Rotatory dislocations of traumatic origin may have not only ligamentous disruption but also bony avulsions or fractures from the C-1 joint surfaces, increasing the degree of instability.

With an infectious etiology, treatment is initially geared toward eradicating the organism responsible with intravenous antibiotics. Treatment is then primarily based on the duration of the deformity at presentation. If the deformity has been present for less than 1 week, place the patient in a soft collar and put him on bed rest. If the deformity does not spontaneously reduce, institute halo traction. The weight initially used is based on the age of the patient: 7.7 lbs (3.5 kg) for younger children and up to 13 to 17.6 lbs (6 to 8 kg) for adults. The weight may be increased in integers of 1.1 lb to 2.2 lbs (0.5 to 1 kg) every 3 to 4 days until reduction is achieved to a maximum limit of 13.2 lb (6 kg) in children (70) and 19.8 lb (9 kg) in adults. If the deformity has been present for more than 1 week, start halo traction immediately. Continue traction for up to 3 weeks, but if reduction is not accomplished, a surgical stabilization procedure in symptomatic individuals is indicated.

If reduction is achieved, continue immobilization to allow the capsules and ligaments to heal. Wetzel and La Rocca (61) devised a protocol for immobilization based on the type of deformity. They recommend a soft collar for type I, a rigid collar for type II, and a halo for types III and IV for a duration of up to 3 months. After treatment, obtain flexion-extension radiographs to document stability.

Surgical intervention is indicated when there is evidence of significant instability or neurologic deficits, when there is failure to achieve or maintain a reduction in an acute traumatic deformity, or if symptoms persist after conservative treatment. A posterior C1–C2 fusion is recommended. In situ fusion is recommended by some, but the presence of superior angulation makes it more difficult because of the narrowed space behind the posterior ring of C-1. Improvement in the cosmetic deformity is usually slow and often occurs through rotation at cephalad and caudal levels, which may become symptomatic in the future. Some surgeons recommend an attempt at open reduction.

**Open Reduction**

- Pass a sublaminar wire under the posterior arch of C-1 and gently applying traction in order to manually derotate the atlas.
- After reduction is achieved, incorporate the wire into a Gallie or Brooks C1–C2 fusion, or C1–C2 transarticular screw fixation can be done. The C1–C2 transarticular screw fixation is the most stable construction to prevent redisplacement if reduction can be achieved either preoperatively or intraoperatively.
- Screw placement is difficult when residual rotatory deformity exists at the time of screw passage.
- If neurologic deficit is present and reduction cannot be achieved, perform a decompression of the posterior arch of C-1, followed by an occipitocervical fusion.

**C-2 Injuries**

**Fractures of the Odontoid (Dens)** Fractures of the odontoid account for approximately 15% of all cervical spine fractures. Neurologic deficits occur in approximately 25% of patients with fractures and can range from quadriplegia to slight neuralgias. There is a higher mortality rate associated with this fracture in elderly patients. In younger patients, these fractures tend to occur as a result of motor vehicle accidents; in older patients, they tend to result from falls. The mechanism is forceful flexion or extension with an axial load. Flexion results in anterior subluxation, whereas extension results in posterior subluxation.

The classification system for dens fractures was described by Anderson and D'Alonzo (2) (Fig. 139.11). A type I fracture is an avulsion fracture at the tip of the odontoid above the transverse ligament. A type II fracture occurs at the junction of the body and dens, and may be transverse or oblique. A type III fracture extends into the cancellous portion of the body of C-2.

**Figure 139.11. Classification of odontoid fractures: Three types of odontoid fractures as seen on AP and lateral radiographs. Type I is an oblique fracture through the upper part of the odontoid process. Type II is a fracture at the junction of the odontoid process with the vertebral body of the second cervical vertebra. Type III is a fracture through the body of the axis. (Redrawn from Anderson LD, D’Alonzo RT. Fractures of the Odontoid Process of the Axis. J Bone Joint Surg [Am] 1974;56:1664, with permission.)**
The treatment of type I fractures is a period of immobilization with a soft collar until symptoms resolve. However a type I fracture may be an indication of a distraction injury at C1–C2 and thus may be a grossly unstable injury requiring C1–C2 arthrodesis. Take flexion-extension radiographs to document stability because some instances of type I fractures are associated with other significant ligamentous injuries that can be grossly unstable. The outcomes are excellent, with few residual symptoms; even persistent nonunion of the avulsion fragment offers no long-term problems.

The treatment of type II fractures is somewhat controversial. The nonunion rate for nonoperative treatment is widely variable (13, 36, 14, 40, 41, 65, 68) and ranges up to 75% in some series. It appears to correlate with several factors:

- Posterior displacement (19)
- Initial displacement of greater than 5 mm (41)
- Inability to obtain or maintain an anatomic reduction
- Advanced patient age
- Pre-existing diabetes or rheumatoid arthritis in the injured patient

In these high-risk patients, initial surgical stabilization is recommended. In addition, the inability to achieve a reduction in traction or the inability to maintain a reduction in a halo vest is an indication for surgical stabilization.

Type III fractures have relatively low nonunion and malunion rates (less than 15%) when treated appropriately (14). Nondisplaced type III injuries can be treated in a rigid collar, but displaced injuries usually require halo vest immobilization for 12 weeks. If the fracture line is oblique, it is generally not possible to correct collapse, but angulation of the soft tissues can be maintained to healing. Obtain flexion-extension radiographs at 12 weeks to document stability. Treat failures of halo treatment with a C1–C2 fusion. Loss of initial reduction is also an indication for fusion.

The most common method of treatment for dens fractures is C1–C2 arthrodesis by either the Gallie (35) or Brooks (12) methods, as previously described. The Gallie method is not indicated for posteriorly displaced fractures. Results of treatment of dens fractures uniformly demonstrate an arthrodesis rate of approximately 90% irrespective of the technique used.

When the posterior arch of C-1 is fractured or the dens fragment is unsteady that it translates both anteriorly and posteriorly, a C1–C2 transarticular screw (59) or a direct anterior osteosynthesis of the dens is necessary (Fig. 139.12). This technique provides increased initial stability when compared with wiring techniques but is technically challenging.

Magefi Fusion C1–C2

- Perform an awake fiberoptic intubation and turn the patient prone. Position the patient’s head in a Mayfield three-pronged head holder. Verify the neurologic status and initiate general anesthesia.
- Set up fluoroscopy so that both AP and lateral images can be obtained, preferably simultaneously. Place the patient’s neck in as much flexion as possible without displacing the dens. Place a guide wire along the neck and image to verify that the trajectory needed can be obtained.
- The position of the neck that can be achieved consistent with reduction of the deformity influences exposure. If the neck can be flexed (Fig. 139.12A1) and reduction achieved (as is the case with a posteriorly displaced dens fracture), then the drill insertion and instrumentation can usually be done through the primary surgical incision. If the neck cannot be significantly flexed and the position maintained, as is often the case with ruptures of the transverse ligament (Fig. 139.12A5), then use a sublaminar wire primary incision with the drills and taps passed percutaneously into the primary incision.
- Make an incision across to the C-4 spinous process, exposing the posterior arch of C-1 to the C2–C3 facet joint. Carefully dissect with a Penfield elevator to expose the pedicle of C-2 all the way up to the posterior capsule of the C1–C2 joint. Remove the joint capsule. This dissection is done by elevating carefully along the proximal edge of the lamina of C-2 in a lateral direction until the pedicle is identified. Take care at this point to sweep the soft tissues proximally over the C-1 lateral mass rather than incise them because the greater occipital nerve and a very friable complex of thin-walled venous lakes overlie those structures. Significant bleeding may occur.
- Clearly dissect the medial aspect of the pedicle (Fig. 139.12B). The landmarks for the starting holes for the drill need to be near the medial edge of the facet and inferior margin of the lamina.
- Hold the soft tissue out of the way by placing a small K-wire below it drilled into the proximal edge of the lamina of C-2 using the guide wire. Drill and tap for 3.5 or 4 mm screw and determine the depth (Fig. 139.12C). The orientation of the drill should be from the medial starting hole to slightly lateral; do this by direct visualization of the path. It is important to monitor the position on the lateral image carefully so that the drill exits the C-2 lateral mass at its posterior aspect (Fig. 139.12D).
- Advance the wire slowly toward the posterior rim of the superior facet of C-2, across the joint, and into the middle or posterior third of the inferior articular process of C-1. Advance the wire toward the superior margin of the anterior arch of C-1. A percutaneous approach through the soft tissues at the C6–C7 level is sometimes necessary to obtain the correct trajectory.
- Use a cannulated screw system to simplify the remaining steps, but take great care because inadvertent advancement of the guidewire can cause significant injury. This method requires constant imaging.
- Drill and tap for 3.5 or 4 mm screw and determine the density (Fig. 139.12F). A 3.5 mm fully threaded screw is most commonly used, with the length varying between 40 and 50 mm, depending on patient size and screw trajectory.
- Next, harvest a rectangular tricortico cancellous bone graft and notch it to fit between the decorticated spinous process of C-2 and posterior arch of C-1.
- Secure it in place with the sublaminar wire previously passed using Gallie technique.

Immobilize the patient postoperatively with a rigid collar for 6 to 8 weeks if no posterior arch fracture is present. If a posterior arch fracture is present or if the fixation is weak, immobilize the patient for 12 weeks in either a halo vest or suboccipital-mandibular immobilization (SOMI)-type brace.

In the interest of preserving as much rotational motion as possible, a direct anterior screw fixation technique has been recommended by some and has shown high union rates, requiring only limited postoperative immobilization (Fig. 139.13) (8, 47). The complication rates, however, have been reported to be as high as 20%. The indications include acute type II fractures and very selected type III fractures without much C-2 body involvement. Contraindications include comminuted fractures, associated unstable ring fractures, atypical oblique coronal fractures, irreducible fractures, and nonunion with poor bone quality. It is essential that the fracture be reducible; reducibility must be verified preoperatively with either fluoroscopy or plain radiographs. A small amount of displacement significantly decreases the area available for insertion of the screw. Large amounts of cervicothoracic kyphosis make this procedure technically unfeasible because adequate space must be available for the contact screw trajectory. This procedure is technically difficult in posteriorly displaced fractures because reduction will be lost as extension of the cervical spine as is required to achieve access to C2. The postoperative range of motion has been shown to still be reduced, possibly secondary to adhesions and callus formation.

Positioning of the patient for anterior dens osteosynthesis is critically important. Place the patient in the supine position with the neck extended so that exposure of the anterior interior of C-2 is possible. Rest the head on a Mayfield horseshoe head support. If fracture reduction is lost (as may happen with posteriorly displaced dens fractures), use less extension until provisional fixation has been achieved. Biplanar image intensification monitoring is essential (Fig. 139.13A). Perform an awake fiberoptic intubation and document the neurologic status. Aid reduction by placing a rolled towel under the neck for anterior displacement and under the head for posterior displacement.

Set up fluoroscopy so that satisfactory AP and lateral views can be obtained; simultaneous imaging is required. When reduction is obtained, make a standard anterior lateral approach through a transverse incision centering the incision at the C5–C6 level (Fig. 139.13B). Make a retropharyngeal approach, as described by Smith-Robinson (see Chapter 139), at the C5–C6 disc space level and carry the dissection up to the C2–C3 disc space. Make an incision in the anterior longitudinal ligament at the level of the inferior portion of the C2 body. A one- or two-screw technique can then be used.

Starting 3 mm to either side of the midline and on the caudal edge of the body, medially insert a 1.5 mm K-wire to ascertain trajectory and stabilize the fragment (Fig. 139.13C). Insert it across the fracture into the center of the odontoid. Two K-wires can be placed and a cannulated system used, but inadvertent advancement of the wire is a complication; preferably, one wire is removed and replaced at a time with a solid 2.5 mm drill bit advancing to the tip of the dens. Pass the drill over the guidewire and advance it under fluoroscopic control. Take care—there have been instances in which the guidewire has been advanced into the spinal cord.

Because a lag effect is desired, either a partially threaded screw can be used or one drill bit can be removed and the fragment overdrilled with a 3.5 mm drill bit (Fig. 139.13D). Tap the near cortex only (Fig. 139.13E, Fig. 139.13F, and Fig. 139.13G). Be sure that all threads of this lag screw are across the fracture site. Final screw fixation should have the screw slightly oblique toward the midline and optionally may perforate the cortex of the tip of the dens (Fig. 139.13H and Fig. 139.13I). Take care to begin the screw on the undersurface and not the anterior surface of the C2 body to achieve the proper trajectory (Fig. 139.13J).

Studies have shown no significant increase in biomechanical stability with two screws, and anatomic studies have revealed that some odontoids are of inadequate size to accommodate two screws (18,28,59). Postoperative immobilization in a Philadelphia collar for 6 weeks is generally sufficient.

**Traumatic Spondylolisthesis of the Axis**

Traumatic spondylolisthesis of the axis is a fracture that occurs through the pars interarticularis usually at its junction with the posterior aspect of the vertebral body. Such fractures are relatively uncommon and the mechanism of injury varies with the fracture type. These usually occur in motor vehicle accidents in which the head strikes the windshield or dashboard. The amount of displacement and angular deformity is related to the amount of rebound occurring from the associated acceleration and deceleration forces. These fractures are generally not associated with significant neurologic deficits because most of the injury patterns expand the canal diameter. As with fractures of the atlas, if a deficit is present, it may be related to a head injury or to some associated injury.

Diligently search for associated injuries that can occur in up to 30% of patients with these fractures. Most of the concurrent injuries occur in the adjacent three cervical levels (56).

Several different classification systems have been used to describe traumatic spondylolisthesis of the axis. The systems have been based on either instability criteria (34), mechanism of injury (56), or anatomic or radiologic criteria (25,56,81). The classification most commonly used now is based on four patterns, each of which has both common radiographic and mechanic characteristics (Fig. 139.14)(56).

**Figure 139.14.** Traumatic spondylolisthesis of the axis can be characterized by the amount of translation and angulation at the fracture site. A: In a type I injury, the fracture line is either vertical or slightly off vertical (arrows). B: In a type II injury, the fracture line is relatively vertical with wide separation of the fragments (arrows). These are characterized by more than 3 mm of translation and significant angulation as well. They frequently demonstrate a compression of the anterosuperior corner of the body of C-3 as a result of the flexion force that caused the anterior translation (star). In this case, avulsion of the anterosuperior corner of the body has occurred. C: Type IIA traumatic spondylolisthesis is different in its mechanism from type I and II injuries. Frequently, the fracture lines are more oblique (arrows) and are not located as close to the junction of the body and the pedicle as in the type I and II injuries. D: Type III traumatic spondylolisthesis of the axis combines fractures of the neural arch with facet injuries at C2–C3. The first type is a bilateral facet dislocation at C2–C3 (star) with a type I Hangman's fracture at the base of the body–pedicle junction (arrowhead). (From Levine AM, Elsmondt FJ, Garfin SR, Zigler JE. Spine Trauma. Philadelphia: W. B. Saunders Co., 1998, with permission.)

A type I injury has a fracture through the pedicles of C-2, just posterior to the junction of the body and the pedicles. A type I injury (Fig. 139.14A) is either a nondisplaced fracture or minimally displaced, with less than 3 mm of displacement and no angulation. It usually results from an axial load with an associated hyperextension moment. The type IA, or atlantal hangman's pattern (81), involves a fracture between the junction of the body and the pedicle of C-2 in which, at least on one side, a portion of the posterior wall breaks off and remains attached to the pedicle. The significance of this pattern is that, if there is any displacement, the cord can be compressed between the ring of C-1 and the retained portion of the posterior wall. The fracture line frequently traverses the foramen for the vertebral artery and may result in intimal damage. A higher incidence of neurologic deficits is associated with this pattern.

The type II injury (Fig. 139.14B) involves displacement and angulation of C-2 on C-3. A type II injury is the result of a hyperextension axial load, which breaks the neural arch, followed by a flexion injury, which results in significant translation. The pattern of the fracture line is similar to that seen with a type I injury.

The type IIA injury (Fig. 139.14C) has only minimal translation of C-2 over C-3 but has severe angulation. The type IIA injury is characterized by minimal translation and significant angulation with widening of the posterior aspect of the disc space. With application of traction, these are the injuries that will demonstrate significant widening of the disc. The mechanism is different in that this type of injury occurs as a result of a flexion distraction force. The fracture line, instead of being vertical at the junction of the pedicle and the body is obliquely through pedicle. Traction may produce distraction, leading to potential neurologic injury.

The type III injury (Fig. 139.14D) is a pars fracture with an associated C2–C3 unilateral or bilateral facet dislocation. The mechanism most probably is initial flexion-distract, which causes the dislocation, and then extension, which causes the traumatic spondylolisthesis. Reversing the mechanism would not permit the dislocation to occur, because the inferior facet of C-2 would then be detached from the cervicozoonum, which serves as the lever for the dislocation. This pattern is associated with a higher incidence of neurologic deficits.

Radiologic evaluation and determination of the traumatic spondylolisthesis can usually be made on a lateral cervical spine roentgenogram. However, because most radiographs of this injury are performed in the supine position, the true nature of the injury may be obscured because any displacement may be reduced in the supine position. Thus, to ensure that the injury is indeed a type I, physician-supervised flexion-extension radiographs are necessary to differentiate it from a reduced type II. In order to undergo flexion-extension radiographs, patients must be awake, alert, and neurologically intact, and able to perform the flexion extension maneuver themselves. Atlantal hangman's fractures may require axial images from a CT scan to fully appreciate the direction and extent of the fracture lines. Finally, in type III injuries, a CT scan with reconstuctions may be necessary to characterize the facet component of the injury.

Treat type I injuries nonoperatively with a rigid collar for 8 to 12 weeks. Late-onset degenerative arthritic changes can occur in up to 30% of patients because the initial injury causes severe impaction forces across the facet joint, which can be destructive to the articular cartilage. Patients with type I injuries do not go on to spontaneous arthrosis across the C2–C3 disc, as is seen in type II injuries. Treat type II injuries with significant amounts of displacement or angulation initially by reducing using skeletal traction in a slight amount of extension followed by a halo vest for 12 weeks. It is not uncommon for some reduction to be lost in the halo vest, but this loss of reduction usually does not lead to any long-term consequences. If the displacement is in the range of 6 to 7 mm, alignment is maintained with a period of 4 to 6 weeks in halo traction, followed by another 6 weeks in the halo vest. Alternatively, after reduction in traction a direct osteosynthesis of the fracture can be accomplished with a lag screw. Treat type IIA injuries with a halo vest placed in compression and extension. This is achieved by placing the halo vest on the patient in a routine fashion and

Anterior Screw Fixation of the Odontoid
then using the bolts on the uprights to compress the ring down toward the vest.

Type III fracture patterns in injuries, in contrast, require immediate surgery. When this fracture pattern is identified, closed reduction should not even be attempted because it is rarely achieved and is potentially dangerous. Even if it is achieved, the remaining instability present is enough to warrant arthrodesis. A preoperative MRI is performed to evaluate the C2–C3 disc. The goal of surgical treatment is to stabilize the C2–C3 facet joint. This can be accomplished with a C2–C3 posterior plate with a C-2 pedicle screw and a lateral mass screw at C-3.

Reduction and Stabilization of a Type III Hangman's Fracture

- Carry out a fiberoptic, awake intubation and turn the patient prone on a Stryker frame. Check the patient's neurologic status and stimulate general anesthesia. Check lateral position on fluoroscopy or plain radiographs. High-quality biplanar fluoroscopy is required to monitor the trajectory of the screw.
- Make a standard approach to the posterior cervical spine from the occiput down to C3–C4 level and expose the C2–C3 and C3–C4 facet joints. Use an elevator to dissect the medial aspect of the C-2 pedicle.
- The facet joint at C1–C2 does not need to be disrupted, but dissection from posterior to anterior toward the facet will usually demonstrate the fracture of the pedicle.
- Then carry out the reduction of the unilateral or bilateral facet dislocation at C2–C3. Place towel clips on the spinous processes of C-2 and C-3. Spread the spinous processes apart with a slight amount of flexion. This should unlock the jumped facets. Apply a posterior translation force to the C-2 spinous process as the towel clamps are brought together to achieve the final reduction.
- A bilateral subluxation is generally easier to reduce than a unilateral subluxation because of the increased ligamentous damage. Traction is not effective in this situation because the break in the pars C-2 prevents any force from being transmitted to the C2–C3 joint level. Rarely, the C2–C3 facets need to be unlocked manually.
- Place a Freer or small Cobb elevator into the facet joint and gently elevate the C-2 facet until it becomes level with the C-3 facet. Then apply a posterior translational force to the towel clip on C-2 as the elevator is slowly removed to achieve reduction. After reduction is obtained, the C2–C3 joint must be stabilized. A standard interspinous process wiring or C2–C3 lateral mass plating can be used; however, the pedicle fracture would then be treated as a type II Hangman's fracture with 12 weeks in a halo vest.
- An alternative method of fixation is to insert a C-2 pedicle screw to secure the pedicle fracture (Fig. 139.15A, Fig. 139.15B, Fig. 139.15C and Fig. 139.15D) (72). If this technique is used, a partially threaded lag screw must be placed so that the threads are beyond the fracture site to prevent any distraction.

Figure 139.15: A: The surgical technique for osteosynthesis of a traumatic spondylolisthesis of the axis. See the text for a description of the technique. B: Orientation of the drills along the pedicle in an axial plane. Slight convergence of the screws is desirable. C: Orientation across the fracture line from the posterior fracture to the anterior fragment. A partially threaded screw, with usually about 15 mm of thread and 20 mm of shank, is desirable. The proximal fragment can be overdreilled and lagged to the anterior fragment. D: The final axial view.

- Before beginning screw insertion, take care that the fracture is as reduced as possible and that a #4 Penfield elevator can be placed along the medial border of the pedicle for guidance.
- Verify the trajectory of the pedicle and the location of the vertebral arteries on a preoperative CT scan. Palpate the medial wall and gently retract the epidural soft tissue medially. The fracture site and posterior body should be seen. Then pass a drill, starting at the center of the facet and directed along the pedicle into the body beyond the fracture site.
- Select a plate of the appropriate length and contour to fit the lateral masses of C-2 and C-3.
- Place a partially threaded screw through the plate across the pedicle fracture. The threads should be beyond the fracture site, and no distraction of the pedicle fracture should be observed. Place a standard C-3 lateral mass screw through the plate.
- A rigid collar for 12 weeks is needed for postoperative immobilization.

Surgery is warranted for the other types of fracture patterns only if there is an associated cervical fracture that requires fixation, if conservative treatment fails, or if the use of a halo is contraindicated. A C-2 pedicle screw (Fig. 139.15A, Fig. 139.15B, Fig. 139.15C and Fig. 139.15D) can be used and offers immediate stability to the fracture. The starting point for the screw is just medial to the C2–C3 facet joint on the anterior table of the lamina. Check the starting point on a lateral fluoroscopic view. A preoperative CT scan is necessary to identify the angle of the pedicle and the location of the vertebral artery. Use a rigid collar for 8 weeks for postoperative immobilization. Anterior arthrodesis for this injury has also been used with mixed results (40,41,47).

The results of treatment are related to the injury type. For type I fractures, union rates approach 98%. Recognition of other associated injuries is important because these fractures can occur with posterior arch fractures or odontoid fractures. The result of these combined injuries follows that of the associated fracture. The most common long-term problem of type I fractures is articular degeneration of the C2–C3 facet joint, which occurs in approximately 10% of injuries. For type IA fractures, the results are related to the fracture pattern but generally are similar to type I fractures. For type II fractures, displacement of 5 mm or more between the anterior and posterior fragments yields a high incidence of nonunion, although more than 70% go on to develop anterior fusions of the disc space. Injuries with symptomatic nonunion and large gaps are generally treated with a towel clip on C-2 as the C2 pedicle screw is removed and require an anterior C2–C3 fusion. The results of type II fractures depend on the severity of the commonly associated head injuries and neurologic deficits. The overall success rate of fusion after reduction is achieved is quite high.

Extension Teardrop Fractures Although a number of different types of "teardrop fractures" have been described since the term was first used by Schneider and Kahn in 1956 (76) the two most common types are the flexion variant, which occurs in the lower cervical spine, and the extension type, which occurs predominantly in the upper cervical spine. The extension type of injury results from a hyperextension and axial loading mechanism and may be observed in combination with posterior arch fractures of the atlas and traumatic spondylolisthesis of the axis. The injury can be easily diagnosed on a lateral roentgenogram of the cervical spine. The triangular fragment usually comprises approximately 50% of the height and 50% of the width of the body. The vertebral body of C-2 remains in normal alignment with the body of C-3, but the avulsed fragment is rotated anteriorly (Fig. 139.16). This is in contradistinction to flexion teardrop injuries, in which the fragment remains in relatively normal orientation to the bodies above and below and the affected body is rotated posteriorly.

Figure 139.16. Extension teardrop fracture.

These injuries are uniformly stable, although they may occur in combination with unstable contiguous injuries in the upper cervical spine. If they occur alone or in
Combination with a stable injury collar, immobilization is sufficient to achieve a satisfactory result. If they occur in combination with an unstable injury, the treatment of the second injury determines the overall treatment.

**PITFALLS AND COMPLICATIONS**

The most important aspect of the management of upper cervical spine fractures is diligent and thorough follow-up of the patients after treatment. Progressive deformities and neurologic deficits are more easily dealt with when recognized early. Union must always be verified with maximum flexion-extension radiographs after treatment. Although posterior wiring techniques are successful, the nonunion rates may be as high as 10%. Take care also with the passage of sublaminar wires because neurologic injury and the sequelae of perforation of one vertebral artery are not as formidable as they were previously thought to be. Clearly, if a vertebral artery injury does occur on one side, do not attempt screw placement on the other side for any reason. Screw malpositions have occurred in approximately 15% of cases, but complications attributable to this problem are rare (less than 2%) and include hypoglossal nerve irritation from excessive screw length, instability from the screws not crossing the joint, and screw breakage.

Anterior odontoid screws are extremely difficult to use and can cause spinal cord injury, cranial nerve injury, and loss of fixation. Other technical problems include incomplete fracture reduction with residual posterior angulation, incorrect screw entry site, and posterior screw angulation. Because of these problems, only experienced spine surgeons should use transarticular or anterior odontoid screws.

The occipitocervical fusion with plate and screws has added significant benefits to traditional wiring techniques. Complications are associated with the placement of the Magerl screw, as described previously. Leakage of CSF is not uncommon with the placement of bicortical occipital screws, but no persistent leaks or significant problems have been reported.

**AUTHORS' PERSPECTIVE**

Injuries of the upper cervical spine encompass a wide spectrum of not only fractures but also patterns of instability that result from ligamentous disruption. The most critical features of the treatment of these injuries are to appreciate the true nature of the instability and the pertinent regional anatomy. Injuries of the upper cervical spine have often been treated more aggressively than necessary (e.g., halo vest for a posterior arch fracture or a Type I hangman's fracture). Surgery is often not necessary if appropriate use of nonoperative modalities is employed.

More recently, however, innovative surgical techniques have appeared that have been applicable to the upper cervical spine injuries. The Magerl C1–C2 translabyrinthine screw fixation has simplified fixation for several different types of injuries. However, the rationale for surgery has sometimes been the desire not to use a halo as the immobilization device. Clearly, the risks and benefits have to be discussed with the patient in an objective fashion before the final treatment decision is made. For example, elderly patients have been reported to have difficult times tolerating a halo as an immobilization device, and physicians have resorted to operative procedures that also have high rates of morbidity.

For example, the use of an anterior dens screw in the elderly patient with a Type II fracture without neurologic deficit may have more morbidity than halo immobilization. More recent studies suggest that less rigid immobilization may yield acceptable patient outcomes without either the risks of surgery or a halo. Accurate assessment of the true significance of the injury and its effect on spine stability will ultimately yield the best patient outcomes.

Each reference is categorized according to the following scheme: *+, classic article; #, review article; 1, basic research article; and *, clinical outcomes study.

Principles of Treatment

INITIAL CARE

Care for a patient with a suspected cervical spine injury begins at the scene of the accident. Carefully move the patient to safety and then immobilize her on a long backboard and apply a rigid cervical collar. Stabilize the head by placing sandbags along each side or use tape to secure the forehead to the board. Paramedics or other emergency management team members often perform the initial assessment and resuscitation.

On arrival to the emergency department, continue resuscitation. Follow advanced trauma life support (ATLS) guidelines. If an airway needs to be secured, take care to prevent further cervical injury by utilizing fiberoptic nasotracheal intubation whenever possible. This technique minimizes movement of the injured cervical spine. Intravenous access is mandatory for fluid resuscitation in cases of neurogenic shock.

Obtain a history from the patient, the paramedics, or witnesses to determine the mechanism of injury and the circumstances surrounding the accident. A history of loss of consciousness is important, as the patient may not be able to accurately recall the events as they occurred. In addition, there is a high correlation between head trauma and cervical spine injuries. Make note of the initial neurologic assessment, with attention to any paralysis.

While the history is being obtained, perform a physical exam. The observation of craniofacial trauma can be important in the assessment of the mechanism of injury. If the patient is conscious, gently palpate the anterior and posterior cervical spine to determine the site of pain or swelling. Palpate the posterior elements in the midline posteriorly, noting any increase in the interspinous distance. Palpate the anterior vertebral bodies in the interval between the sternocleidomastoid and the trachea.

Perform a detailed neurologic examination. Note the general state of consciousness as well as respiratory status. The C-3 to C-5 levels innervate the diaphragm. Cord injury above the C-5 level may lead to respiratory failure. If the patient is conscious, perform motor, sensory, and reflex examination of the upper and lower extremities. The American Spine Injury Association (ASIA) spinal cord injury assessment form (Fig. 140.1) provides an excellent checklist to ensure completeness. Use rectal tone and perianal sensation to assess for the presence of sacral sparing. Document the absence or presence of the bulbocavernosus reflex for the determination of spinal shock.

---

In Bohlmans evaluation of 300 cervical spine injuries, 100 were initially missed at the time of presentation (7). Delay in diagnosis ranged from 1 day to 1 year. The common causes for lack of recognition were concomitant closed head injuries, multiple traumatic injuries, alcohol intoxication, and initial misdiagnosis such as cerebrovascular accidents. An alteration in consciousness contributed to the lack of proper evaluation and failure to take appropriate radiographs. Patients with these injuries often do not complain of pain, and facial and neck lacerations may detract from the evaluation of the cervical spine. Nevertheless, the physician always must suspect a cervical spine injury any time there is associated head trauma (7, 18).

**RADIOGRAPHIC EVALUATION**

As part of the initial trauma assessment, obtain the lateral view of the cervical spine, anteroposterior (AP) view of the chest, and AP view of the pelvis. Approximately 80% of cervical spine fractures can be diagnosed on the initial lateral view if it is adequately done (49, 53). Once the patient is stabilized, complete the remaining views of the cervical spine trauma series. This includes the AP, open-mouth odontoid, and bilateral obliques or pillar views. The lateral view must extend to the C7–T1 level to be considered complete (7, 36). A swimmer’s view may be required to visualize the C7–T1 level in patients with short necks. If visualization still remains questionable, perform a computed tomography (CT) scan (59).

Scrutinize all radiographs carefully for abnormal alignment or fractures. The presence of retropetrophygeal soft-tissue swelling is important and may indicate adjacent fractures or ligamentous injuries (28). Loss of facet parallelism, facet overlap, or widening of the distance between adjacent vertebrae may also indicate ligamentous injury. If abnormalities are noted, a CT scan is helpful in defining the compromised structures and the presence of bone or disc fragments within the spinal canal. Ligamentous injuries are best visualized by magnetic resonance imaging (MRI) performed within the first 72 hours (23, 45).

**ANATOMY**

The vertebrae from C-3 to C-7 are anatomically similar. Little inherent stability is achieved from the interrelationships of the osseous structures, and therefore the integrity of the supporting ligaments is very important (34, 40). The anterior and posterior longitudinal ligaments span the length of this region and are firmly adherent to the annulus fibrosis at each level. These ligaments, along with the annulus, are the primary stabilizers of the anterior column. Posteriorly, the interspinous, supraspinous, and facet joint capsules comprise the primary ligamentous stabilizers. The ligamentum flavum becomes important at the extremes of motion (66).

The anterior structures, including the anterior longitudinal ligament and the annulus fibrosis, act as a tension band during extension. Similarly, the posterior longitudinal ligament, supraspinous and interspinous ligaments, and facet capsules act as a tension band in flexion (67). Flexion compresses the anterior column and tensions the posterior column, whereas extension tensions the anterior column and compresses the posterior column. Thus, the anterior and posterior columns are reciprocally affected by sagittal plane motion (27).

Approximately 50% of the flexion and extension arc of the cervical spine is achieved through the occipital cervical articulation. The remainder occurs through the lower cervical vertebrae, ranging from 8° to 17° at each motion segment. Rotation is equally shared between the atlantoaxial joint and the lower cervical vertebrae. Lateral bending in the subaxial region ranges from 4° to 11° at each segment (69).

**CLASSIFICATION**

The most widely used classification system of lower cervical spine injuries was published by Allen et al. in 1982 (3). In a retrospective review of 165 cases of lower cervical spine injury, they developed a mechanistic system of classifying closed indirect fractures and dislocations.

Injuries are divided into six groups, each named according to the dominant force vector leading to failure and the position of the cervical spine at the time of injury (Fig. 140.2). The groups include compressive flexion, vertical compression, distractive flexion, compressive extension, distractive extension, and lateral flexion. The three most common groups are compressive flexion, distractive flexion, and compressive extension. The least common are distractive extension and lateral flexion, with vertical compression falling between. Compressive indicates that compressional accounts for the initial structural failure in a motion segment, whereas distractive indicates that tension is the dominant force. The use of flexion or extension denotes the position of the cervical spine at the time of injury (3).

Each group is then classified into various stages, with the higher stages reflecting a greater degree of instability (3). Although the degree of neurologic injury cannot be correlated with the staging, the risk of injury is certainly greater in the advanced stages.

**Compressive Flexion**

Five stages are recognized in the compressive flexion (CF) group. The force vector is directed anteriorly and inferiorly. In CFS1 injuries, mild blunting of the anterior-superior vertebral body is noted, caused by compression of the more superior vertebrae. In CFS2, the anterior vertebral body loses additional height and becomes wedged, but still without disruption of the posterior ligamentous structures. In CFS3, a fracture line passes obliquely from the anterior vertebral surface to the inferior endplate without displacement. CSF4 injuries have subluxation and displacement of the posterior vertebral wall into the spinal canal, but not exceeding 3 mm. CFS4 injuries involve severe displacement of the body fragment into the canal, as well as increased interspinous distance, facet subluxation, and posterior longitudinal ligament disruption (3).

CFS1 and CFS2 injuries are usually stable and can be treated nonoperatively (47). CFS3–5 injuries may be unstable, and operative intervention may be required to limit late instability (12, 13).

**Distractive Flexion**

Four stages are recognized within the distractive flexion (DF) group. The force vector is directed anteriorly, away from the trunk, with the neck flexed. In DFS1 injuries, posterior ligamentous disruption with facet subluxation and increased interspinous distance is noted. DFS2 represents a unilateral facet dislocation and DFS3 a bilateral facet dislocation. In DFS4, the superior vertebral body is displaced anteriorly, the full width of the body, creating a “floating” vertebra (3).

All distractive flexion injuries should be considered potentially unstable, although DFS1 injuries can commonly be treated nonoperatively. DFS2–4 commonly require operative intervention to prevent late instability (5, 7, 22, 44).

**Compressive Extension**

Five stages are recognized in the compressive extension (CE) group, although the distinction between the latter stages remains unclear. Unilateral vertebral arch fracture with or without displacement is found in CES1 injuries. Bilateral involvement distinguishes CES2. In CES3–5, comminution of the lamina and lateral masses...
occurs with vertebral or disc space separation. In CES5, complete anterior displacement of the superior vertebral body is noted (2).

CES1 and some CES2 injuries may be treated nonoperatively. However, the higher stages, especially CES5, usually require operative stabilization.

**Vertical Compression**

Three stages are recognized in the vertical compression (VC) group, in which the force vector is axial. In VCS1 injuries, a fracture occurs through either the superior or the inferior endplate. VCS2 involves a fracture through both endplates, but with minimal displacement. In VCS3, further compression causes the fracture fragments to displace peripherally, possibly through a tear of the posterior longitudinal ligament (3).

The majority of these injuries have a high rate of healing when treated nonoperatively. However, VC3 injuries with canal compromise require operative decompression and stabilization (1,2).

**Distractive Extension**

Two stages are identified in the distractive extension (DE) group, in which the force vector is directed posteriorly, away from the trunk, with the head in extension. DES1 injuries involve either a transverse fracture through the vertebral body or disruption of the anterior ligamentous complex. DES2 consists of failure of the posterior ligamentous structures with displacement of the superior vertebral body into the canal (3).

DES1 injuries involving fracture of the vertebral body often heal nonoperatively without deformity. DES2 injuries, however, often require operative intervention.

**Lateral Flexion**

Two stages are identified in the lateral flexion (LF) group, in which the force vector is directed laterally. In LFS1 injuries, an ipsilateral vertebral body fracture and neural arch fracture are noted, without displacement. LFS2 progresses to displacement (3). Treatment depends on the extent of the injury, but most LFS1 injuries may be treated nonoperatively.

**CRITERIA FOR INSTABILITY**

White and Panjabi (55) have defined clinical instability as the “loss of the ability of the spine under physiologic loads to maintain relationships between vertebrae in such a way that there is neither initial nor subsequent damage to the spinal cord or nerve roots, and in addition, there is neither development of incapacitating deformity nor severe pain.” In this definition, physiologic loads are those incurred during normal daily activity. Incapacitating deformity is defined as gross deformity that the patient finds intolerable. Severe pain is that which cannot be controlled by nonnarcotic medications.

In an effort to systemize this evaluation of clinical instability, White et al. (58) devised a checklist, incorporating both clinical and radiographic parameters. Radiographic parameters for ligamentous instability were established through biomechanical studies. Using fresh cadaveric specimens, serial sectioning of the posterior and anterior ligamentous structures was performed. Abnormal motion of the adjacent vertebrae was then measured. In an otherwise intact spine, instability was defined as translatory displacement of two adjacent vertebrae greater than 3.5 mm, or angulation greater than 11° compared with adjacent motion segments. Based on these and other results, a comprehensive checklist was developed for assessing traumatic instability.

According to this checklist, both clinical and radiographic findings are assigned point values. Assign two points each for anterior elements destroyed or unable to function, posterior elements destroyed or unable to function, relative sagittal plane translation greater than 3.5 mm, relative sagittal plane rotation greater than 11°, positive stretch test, or spinal cord damage. Assign one point each for nerve root damage, abnormal disc space narrowing, or dangerous loading anticipated. If the total point value is equal to or greater than five, assume instability of the motion segment (5d).

Although checklists may be useful in the systematic determination of spinal instability, each case should be assessed individually; the importance of certain criteria may vary depending on the specific situation. Of prime importance is spinal cord integrity. When spinal cord injury is caused by extruded bone fragments, or deformity resulting from ligamentous disruption, assume instability. Evidence of isolated nerve root compromise is a weaker indicator of instability.

The stretch test can be particularly useful for evaluating the integrity of the ligamentous structures of the middle and lower cervical spine. This test is performed as follows:

- Apply traction through the use of secure skeletal fixation or a head halter device.
- To reduce frictional forces, place a roller under the patient's head.
- Place the radiographic plate 14 inches from the patient's spine and the tube 72 inches from the plate.
- Take an initial radiograph to ensure no occipit to C-1 to C-2 subluxation.
- Add a 10-pound weight and obtain a lateral radiograph.
- Repeat this process, increasing the traction by 10-pound increments until reaching one third of the body weight, or 65 pounds, whichever is less.
- After each additional weight application, check the patient for any change in neurologic status. If there is a change in status, stop the test. The test is then considered to be positive.

Radiographs are evaluated for any abnormal separation of the anterior or posterior elements. An abnormal test is indicated by differences either greater than 1.7 mm of interspace separation or 7.5° of change in the angle between vertebrae (35). An interval of at least 5 minutes should be allowed between incremental weight applications to allow for creep of the viscoelastic structures. The test is contraindicated in a spine with obvious clinical or radiographic instability.

**INDICATIONS FOR TREATMENT**

Management of lower cervical spine injuries must proceed in an orderly fashion to minimize morbidity and mortality. At the time of initial evaluation and resuscitation, immobilize the injured spine as medical stabilization is implemented. Assess spinal alignment and correct it if necessary. Perform operative decompression if indicated and consider the long-term stability of the injured spine. If the injured segment or multiple segments are unstable, operative stabilization is necessary.

If significant malalignment is noted on initial radiographs, realignment is indicated to relieve any pressure on the neural elements, limiting ischemia and edema formation. Examples of exact significant malalignment are debatable; however, sagittal translation greater than 3.5 mm or angulation greater than 11° would seem reasonable. In addition, realignment or traction would also be indicated in injuries in which extruded bone or disc fragments were contributing to spinal cord or nerve root compromise, even though no significant angulation or translation were present. Reduction can usually be established by skeletal traction with tongs in the skull (15).

- After the tongs are applied in a sterile fashion, apply an initial weight of 10 pounds of traction with appropriate analgesia.
- Perform a detailed neurologic examination and obtain a lateral radiograph.
- Perform careful evaluation of the occipit to C-1 to C-2 levels to ensure no concomitant injury to this region.
- If reduction is not achieved, add weight in 5-pound increments and repeat the process each time.
- Once reduction is obtained, reduce the weight to 15–20 pounds and obtain a repeat radiograph to confirm maintenance of reduction.
- Continue traction until a definitive treatment plan is chosen.

If closed treatment with traction of up to two thirds of body weight or 65 pounds (whichever is less) is unable to achieve adequate reduction, operative intervention is usually required. In cases of facet dislocation, closed manipulative reduction may be an option when traction alone fails to reduce the dislocation. This should be performed only by surgeons experienced in these techniques to minimize the risk of, or exaggeration of, neurologic injury.

Cervical vertebral body dislocations are associated with substantial disruption of the anterior and posterior ligamentous structures and clinical instability. Patients who are undergoing realignment in traction must be constantly monitored and examined to prevent iatrogenic injury to the neural elements resulting from excessive stretching across injured segments. Traction weights should begin at 5 pounds and progress cautiously in order to ensure that overdistruction does not occur.

**INDICATIONS FOR NONOPERATIVE TREATMENT**
In patients with no compression of the neural elements and in whom the stability of the spine has not been jeopardized, a course of bracing in a rigid orthosis for 6–12 weeks may be appropriate. Injuries included in this category are mild compression fractures of the anterior elements and isolated fractures of the posterior elements or lateral masses. Mild vertical compression fractures may require halo immobilization. Follow-up radiographs must be obtained at regular intervals to assess healing. If instability is noted on follow-up radiographs, operative intervention is required.

**INDICATIONS FOR URGENT OPERATIVE INTERVENTION**

In general, early operative intervention for lower cervical spine injuries is indicated in all cases for which decompression is necessary to restore or preserve spinal cord function, and if stabilization is required to prevent further cord or root injury (8,42). Schneider et al. (43) formulated their criteria for urgent operative intervention in patients who had sustained cervical spinal cord injuries. The criteria they deemed important included documented progression of neurologic signs and complete block of the subarachnoid space on myelography. Cooper and Ransohoff (15) included any myelographic evidence of spinal cord compression by hematoma or by bone or disc elements after alignment had been optimized.

Urgent operative intervention is not indicated in a patient with a complete neurologic deficit with loss of motor function distal to the injured segment. Such a patient is unlikely to achieve functional recovery, and operative intervention to stabilize the spinal column may be delayed until he is medically stable. However, urgent decompression of compromised nerve roots may be required in some such patients to preserve an additional neurologic level. Urgent stabilization of the spinal column may also be necessary to facilitate the treatment of other system injuries.

**SURGICAL TECHNIQUES**

When operative intervention is required, the choice of the procedure depends on the nature of the injury and the goals of the surgeon. In general, approach the fracture from the site of major instability (47,51,55). If the injury involves the anterior longitudinal ligament, vertebral body, or disc, an anterior approach is most appropriate. If there is posterior ligamentous involvement or posterior element fractures, a posterior approach is preferred. Sometimes, combined anterior and posterior approaches are required (17). Perform a stabilization procedure at the site of decompression.

**POSTERIOR INSTRUMENTATION OPTIONS**

The two most common posterior stabilization methods use posterior cervical wires or cables and lateral mass plates. In recent years, multistrand stainless steel or titanium cables have replaced traditional stainless steel wires. Multiple studies have shown that cables are stronger, more flexible, and more fatigue resistant than wires (19,28,46). However, the cables are also more expensive. In addition, the added bulk of the crimping device may detract from its use in certain situations. Most posterior wiring techniques require intact posterior arches and spinous processes across the levels to be fused. To provide sufficient spinal stability, the anterior column should be capable of weight bearing, and excessive rotational forces must be avoided (14,24). When these conditions are not present, lateral mass plates are preferred (31). However, it should be kept in mind that a real risk to the spinal cord, nerve roots, and vertebral arteries exists with lateral mass plating. Posterior cervical wiring techniques have fewer risks and years of proven success (11,52).

Most posterior wiring techniques used today have evolved from the interspinous technique reported by Rogers in 1942 (39). In his description, a wire was passed through and around the base of adjacent spinous processes. Corticocancellous bone grafts were placed under the wires, across the interlaminar space to facilitate fusion. Figure 140.3 diagrams the use of a flexible multistrand cable in a procedure similar to that presented by Rogers (see Rogers's technique in the next section).

**Figure 140.3.** Interspinous technique using flexible multiple cables. A: Pass cable 1, near to far, through the C-4 drill hole. Loop it around cephalad edge of the C-4 spinous process, and then pass through the hole again, near to far. B: Then pass cable 1, far to near, through the C-5 hole, loop it around the caudal edge of the C-5 spinous process, and then pass through the hole again, far to near. C: Apply crimp to achieve single interspinous wiring. D: The bone is then in place under the parallel interspinous portions of the cable.

Bohlman’s triple-wire technique is a modification of Rogers’s, in which an additional two wires are used to secure the bone graft to the lamina and spinous processes (30). Bohlman’s modification results in increased flexural and torsional stiffness that is superior to Rogers’s wiring technique and to sublaminar wiring techniques (Fig. 140.4, Fig. 140.5 and Fig. 140.6).

**Figure 140.4.** Interspinous technique using two additional wires. A: Pass the upper and lower wires through the drill holes in the C-4 and C-5. B: Cinch the bone grafts simultaneously onto C-4 and C-5. C: The bone grafts are then in position.
Figure 140.5. A: Lateral radiograph of a 40-year-old lumberjack struck on the back of his neck by a falling tree. There is anterior subluxation of C-4 on C-5. The anterior subluxation was not adequately held despite the application of a halo vest. B: Lateral radiograph after posterior reduction and triple-wire stabilization from C-3 to C-6. Notice that there are two wires linking the facet joints at C4–C5 and a midline tethering wire bridging the base of the spinous processes from C-3 to C-6. There are no sublaminar wires. C: AP radiograph showing the lateral interfacet wires and the midline tethering wires. The patient at 1-year follow up was neurologically completely intact and his spine was completely fused. He returned to work as a lumberjack doing heavy manual labor.

Figure 140.6. A: Axial CT image of a 25-year-old man who sustained a diving injury. The patient has a fracture dislocation of the left C-3 facet joint. The inner aspect of the lamina is seen compressing the posterior aspect of the spinal cord. He had numbness on the left side of his neck in the C-3 nerve distribution. In addition, he was hyperreflexic throughout, secondary to a myelopathic lesion. B: The patient underwent a posterior decompression and triple-wire stabilization from C-2 to C-4. This axial postoperative CT image shows the posterior wiring and bone graft that stabilized the spine. Notice the adequacy of the decompression of the spinal canal. C: AP radiograph of the triple-wire stabilization technique from C-2 to C-4. The lateral wires hold two corticocancellous bone grafts in compression against the posterior aspects of the lamina at C-2 and C-4. D: Postoperative lateral radiograph shows a solid fusion from C-2 to C-4 with good spinal alignment aside from the patient's original 15% subluxation at C3–C4. The patient was neurologically completely intact, and his spine was stable at long-term follow-up.

When the lamina and spinous processes are compromised by injury or decompression, Rogers’s and Bohlman’s techniques cannot be used. An alternative to lateral mass plating is facet wiring, reported by Robinson and Southwick in 1960 (38), and modified by Callahan in 1977 (Fig. 140.7) (11). In this technique, the articular processes are denuded and wires are passed through the inferior articular processes, which are then secured to overlying bone graft. In the case of rotational instability, or when there is a one-level lamina fracture, oblique facet wiring is an option (Fig. 140.8) (10,21). Wires are placed through the inferior facet as described earlier in the facet wiring technique, but then secured to the next inferior spinous process instead of overlying bone graft. Bilateral wiring from the facets to the inferior spinous process is recommended.

Figure 140.7. Facet-wiring technique. A and B: Holes are drilled at a 90° angle to the articular surface. A: AP view. B: Lateral view. C and D: A curved rib graft or a portion of the iliac crest is used to create a cervical lordosis. C: AP view. D: Lateral view. E and F: Free wires emanate from the caudal end of the spinous process and are securely fixated to the graft or rod. E: AP view. F: Lateral view.

Figure 140.8. Oblique facet wiring. A small drill is used to create a hole in the inferior articular process at a 90° angle to the articular surface. (Inset) Wires in place in the drill holes after being tightened and securely fixated.

Lateral mass plating is considerably more demanding than posterior wiring techniques. Plates are fixed to the lateral masses by screws placed at each level. Two methods of screw placement are commonly used, the original technique described by Roy-Camille et al. (41) and the Magerl technique (29). Of the two techniques, Magerl’s is more commonly used because it provides a stronger and stiffer construct (Fig. 140.9) (32).

Figure 140.9. Screw direction for the Magerl and Roy-Camille techniques.
POSTERIOR FUSION

If the patient was previously placed in tongs, maintain traction throughout the case. Fiberoptic intubation is preferred to minimize any movement of the unstable spine.

- Following intubation, turn the patient prone on a spine-turning frame. If possible, keep her awake until after she is prone to monitor for any neurologic changes.
- Intraoperative neurologic monitoring (e.g., for somatosensory evoked potential [SSEP]), is helpful in identifying changes.
- Hold her face in a Mayfield head holder or other similar device.
- Tuck her arms at her sides. With 3-inch tape, secure her shoulders down to the foot of the bed with a gentle longitudinal pull. This permits radiographic visualization of the lower cervical spine.
- Obtain a preoperative radiograph in the prone position to verify spinal alignment.
- If the injured levels are difficult to identify intraoperatively, use radiographic localization.
- Decompress the areas dictated by the preoperative studies, and perform one of the following fusion techniques.
- After the stabilization procedure, obtain a radiograph to assess the reduction and to confirm the levels of fusion.
- Close the wound in layers over a drain.
- Continue prophylactic antibiotics for 24–48 hours.
- Continue postoperative traction for 24–48 hours, and then immobilize the neck with a hard collar or two postcraniorthosis, depending on the adequacy of the stabilization construct.

Rogers's Technique

- Using a burr, make a hole in the midportion of the base of each spinous process to be included in the fusion. Avoid penetration of the laminae.
- Place a pointed towel clip through each hole to confirm adequate room for passage of the cable.
- Drill the pilot hole with a 2 mm drill bit, aiming parallel to the articular surfaces and approximately 25° laterally.
- Pass a cable through this hole from a posterior to anterior direction and grasp it from within the joint to deliver it into the field.
- Place the bone grafts underneath the cables, spanning the interlaminar space.

Bohman’s Triple-Wire Technique

- Place the first cable as described for Rogers's technique.
- Place the remaining two cables through and around the most superior and inferior spinous processes to be included in the fusion (Fig. 140.3).
- Drill a hole at 45° off the horizontal through the inferior facet.
- Drill a 3 mm hole at 45° off the horizontal through the inferior facet.
- Pass a wire through a hole in the most superior spinous process, and then wrap the cable around the spinous process and reenter the hole from the same direction (Fig. 140.3). This creates a tethering loop around the spinous process, decreasing the chance of the cable cutting out of the bone.
- From the opposite direction, pass the wire through the next spinous process to be included in the fusion, and follow a similar technique.
- Repeat this process bilaterally at each level to be included in the fusion.
- Before the graft is placed, remove all the soft tissue covering the lamina and roughen the bone surfaces with a burr to allow fusion to occur.

Facet Wiring Technique

- Identify each articular facet to be included in the fusion.
- Using a small, thin elevator, pry open the joint and rotate the elevator to maintain exposure of the joint surfaces (Fig. 140.7).
- Drill holes toward each end of the previously harvested corticocancellous grafts.
- Denude the surfaces with a burr to facilitate fusion.
- Pass the bone grafts underneath the cables, spanning the interlaminar space.

Oblique Facet Wiring

- Drill a hole through the inferior articular facet as described for facet wiring.
- Drill an additional hole through the base of the next inferior spinous process (Fig. 140.8).
- After passing the cable through the facet, pass it through and around the spinous process.
- Place the bone grafts underneath the cables, spanning the interlaminar space.

Lateral Mass Plating

- Using the Magerl technique, identify the four borders of each lateral mass to be included in the fusion. The medial border is the valley at the junction of the lamina and the facet. The lateral border is the far edge of the articular mass. The superior and inferior borders are the respective facet joints. The starting point is 1–3 mm medial to the center of the four borders of the lateral mass (Fig. 140.9).
- Direct the drill bit 30° to 40° superiorly, parallel to the facet joints, and 25° to 30° laterally. Use bicortical purchase and breach the far cortex by the “loss of resistance” technique with an oscillating drill. A depth gauge accurately assesses the length of screw needed, which is generally 16–22 mm. The vertebral artery is located directly anterior to the valley at the junction of the lamina and articular mass. Avoid this artery by aiming the screws laterally. Avoid the nerve roots by keeping the screws within the articular masses, aiming parallel to the articular surfaces.
- Place the most superior screw in the construct, as described for the Magerl oblique facet wiring technique.
- Drill the pilot hole with a 2 mm drill bit, aiming parallel to the articular surfaces and approximately 25° laterally.
- Use the depth gauge to measure the length of the hole.
- Insert the appropriate-length screw and tighten moderately.
- Screw placement for the remaining articular masses will be somewhat dictated by the plate hole configuration. Place the remaining screws in a fashion similar to the first one.
- Tighten all screws securely at the end of the procedure.
- Denude the joints with a burr and apply local bone graft prior to plate placement.

In cases of spinal instability across the cervicothoracic junction, extension of the posterior plating construct to the upper thoracic vertebra can be achieved. Fixation to the thoracic spine may be through the use of pedicle screws or hooks, depending on which plate or plate–rod construct is utilized. If pedicle screws are desired, the placement technique must be changed from that used for lateral mass screws (Fig. 140.10). Aim the upper thoracic pedicle screws 25° to 30° medially, with the starting point at the intersection of the midportion of the facet joint and the midportion of the transverse process. Thoracic pedicle screw placement is demanding and should be performed only by surgeons experienced in these techniques.
ANTERIOR INSTRUMENTATION

In the early 1950s, Robinson began his work on anterior approaches to the cervical spine in animals and cadavers (37). Currently, the Robinson anterolateral approach between the carotid sheath and the esophagus is optimally suited for access to levels C-3 to C-7. With exacting technique, it is possible to reach as superior as the second cervical vertebra and as inferior as the second thoracic vertebra. In fracture management, this approach is suited for decompression of herniated disc material and of retropulsed fragments from compressed vertebral bodies.

Anterior plates are commonly used for stabilization after decompression for traumatic injuries. Without instrumentation, loss of reduction and graft displacement occur in up to 64% of anterior decompression and strut graft reconstructions (2,6,26,48). The first-generation anterior cervical plates required bicortical purchase of the screws because there was no mechanism for locking the plate–screw interface. This problem was solved with the second-generation plates, which do not require bicortical purchase of the screws and have a rigid plate–screw interface. Morscher et al. (33) established the concept of the cervical locking plate—that is, a rigid plate–screw interface. A variety of second-generation systems are available today.

ANTERIOR FUSION

- If the patient has previously been placed in traction, maintain traction for the remainder of the case.
- Use fiberoptic equipment to insert a nasotracheal or endotracheal tube, avoiding manipulation of the unstable cervical spine during intubation.
- Position the patient carefully on the operative table. Tuck his arms at his sides and tape his shoulders down to the foot of the bed to permit radiographic visualization of the lower cervical levels.
- Obtain a preoperative lateral radiograph to check alignment.
- Prepare the skin aseptically from the chin to the nipple line bilaterally, as well as the anterior iliac crest for graft harvesting.
- Identify the carotid tubercle of the C-6 vertebra (Chassaignac's tubercle) for orientation purposes. If this is not palpable, the hyoid bone overlies C-3, thyroid cartilage is at C-4 to C-5, and cricoid cartilage localizes C-6. Use these landmarks to adjust the position of the skin incision in relation to the injured level.
- Make a transverse incision on the left or right side of the neck, whichever is preferred, extending from the midline to just past the anterior border of the sternocleidomastoid. Alternatively, use an oblique incision along the anterior border of the sternocleidomastoid to approach several levels (Fig. 140.11, Fig. 140.12). The rationale for approaching on the left side of midline is that the recurrent laryngeal nerve ascends in the neck on the left side between the trachea and the esophagus, having branched off from its parent nerve, the vagus, at the level of the arch of the aorta. On the other hand, the right recurrent laryngeal nerve travels alongside the trachea in the neck after passing beneath the right subclavian artery. In the lower part of the neck, the right recurrent laryngeal nerve is vulnerable to injury as it passes from the subclavian artery to the tracheoesophageal groove. Its course in the groove is also more variable on the right than on the left. Therefore, there is theoretically less risk to the recurrent laryngeal nerve by using the left-sided approach. However, the approach on the left has the possibility of injuring the thoracic duct, which enters the jugular vein–subclavian vein junction at the base of the neck on the left.

ANTERIOR SPINE

- Identify and elevate the platysma, incising it in line with the incision using Metzenbaum scissors.
- Next, incise the superficial layer of the deep cervical fascia along the anterior border of the sternocleidomastoid. Proper exposure is necessary to facilitate mobilization of the underlying structures. The omohyoid muscle traverses the field and can be retracted or divided as necessary.
- Palpate the arterial pulse to identify the carotid artery within its investing sheath.
- The middle layer of the deep cervical fascia is the next important layer to be divided. Divide it longitudinally, medial to the carotid sheath. Identify the carotid artery (by using your fingers), and protect it as this layer of fascia is divided. Retract the artery laterally, along with the internal jugular vein, vagus nerve, and phrenic nerve.
- Carry blunt dissection through the loose areolar tissue to the anterior cervical spine.
- Identify the esophagus mediially, and retract it with a blunt Richardson retractor. Use a thyroid retractor to retract the carotid sheath and sternocleidomastoid laterally.
- Identify and protect the recurrent laryngeal nerve, which descends along the carotid sheath and ascends between the trachea and esophagus. This structure can be injured with sharp retractors or prolonged pressure.
- The midline of the anterior cervical spine can be palpated, as well as the anterior carotid tubercle at C-6. This landmark can be helpful in localizing the injured vertebrae. Transect the alar and prevertebral fascia vertically in the midline, revealing the underlying anterior longitudinal ligament. The longus colli is visible along the lateral aspects of the anterior cervical vertebrae.
- Perform subperosteal dissection to the lateral edge of the vertebrae of the injured levels.
OPERATIVE

1. Confirm the appropriate level with an intraoperative radiograph.
2. After radiographic verification of the appropriate level, perform a decompressive procedure at the injured levels. Incise the disc with a #11 blade and remove it with curets and rongeurs. Complete excision of the disc is essential to gauge the proper depth to the posterior longitudinal ligament. If a corpectomy is required, excise each adjacent disc first and then remove the intervening bone. The posterior longitudinal ligament is usually disrupted in unstable injuries. Remove all bony fragments within the canal under direct visualization. Take care to avoid bone or disc excision lateral to the uncovertebral joints, to avoid injury to the vertebral arteries.
3. After completing the decompression, use a burr to roughen the endplates to be included in the fusion to expose bleeding cancellous bone. Make a small trough in each endplate to accommodate pegs fashioned on either end of the tricortical iliac crest bone graft. Insert the graft with the pegs in the vertebral bodies with the cortical surfaces placed posteriorly to give maximal stability and to prevent collapse.
4. After placement, obtain a radiograph to confirm reduction and placement (Fig. 140.13).

**Figure 140.13.** Decompression of the cervical cord should include excision of the discs above and below the burst fracture and the appropriate vertebral body. B: The endplates should be undermined to allow the tricortical iliac crest graft to be countersunk.

- An anterior cervical plate may be added based on the amount of instability. Choose the length of the plate by using the provided template. Place the plate in the appropriate position, spanning the grafted area. Be sure that the longitudinal center of the plate is midline, not displaced to one side or another.
- Position the drill guide in its correct orientation, as dictated by the manufacturer’s instructions. Usually, the drill guide is aimed medially 20°, with the sagittal angle determined by the position of the plate. Drill to a preselected depth, taking care to remain in bone at all times.
- After tapping, place the screw and tighten moderately. Place two screws in each vertebral body at the ends of the construct. Additional screws may be added in the graft. Tighten all screws and engage the locking mechanism. Radiographic confirmation of correct screw placement is advised.
- Place a large Penrose drain into the depths of the wound. Close the platysma with interrupted sutures and the skin with subcuticular sutures. Keep a tracheostomy set at bedside for 48 hours in case of hematoma formation, which may obstruct the airway. Remove drains at 48 hours.
- Keep the patient in traction overnight, and then place the neck into a hard cervical collar or halo, depending on the amount of instability and the stabilization achieved. Continue immobilization for 3 months or until union is achieved.

**PITFALLS AND COMPlications**

Complications associated with the care of patients with lower cervical spine injuries can be numerous and involve many systems. Comprehensive care must be given to prevent or minimize these complications, especially those that may be iatrogenic in origin.

**NEUROLOGIC**

It is essential to identify cervical spine injuries in trauma victims at the time of initial evaluation to prevent neurologic injury. Keep the patient immobilized at all times to prevent further injury to the spinal cord or nerve roots. Placement of an orthosis or halo apparatus must be done in an organized and efficient fashion to avoid further damage.

As cervical spinal injuries are common in patients with associated cervical spondylosis and ankylosing spondylitis. It can be seen at any time after injury and is usually secondary to ascending central necrosis of the gray matter, with an enlarging central syrinx. The diagnostic modality of choice is MRI.

**SPINAL DEFORMITY**

Reduce any fractures and dislocations as expeditiously as possible by traction or operative means. If the deformity is not reduced, additional spinal cord or nerve root injury can occur by compression or edema. In addition, compression of the radicular arteries to the cord can precipitate ischemia and further worsen the neurologic injury.

Monitor the neurologic status of the patient at the time of the reduction because disc material and bone fragments may be pushed into the canal, causing further neural injury. If the reduction is performed nonoperatively, serial neurologic examinations provide adequate information regarding neurologic function. If operative reduction is required, neurologic monitoring (e.g., SSEPs or an electromyogram) is useful. Should a neurologic deficit occur following a closed or intraoperative reduction, operative decompression of the affected area is indicated.

If no neurologic deficit is noted initially with a unilateral or bilateral facet dislocation, a prerequisite MRI is beneficial to identify extrusion of the disc material into the canal (22). If this is found, the authors recommend an anterior disectomy prior to reduction to minimize iatrogenic injury to the cord. A delay of reduction to perform imaging is of little benefit to the patient with a spinal cord injury (25). In cases with concomitant spinal cord injury, perform MRI after reduction. Carefully evaluate chronic dislocations with an intact neurologic status prior to any treatment. Operative fusion in the dislocated position may be required to prevent neurologic injury caused by reduction.

Carefully follow all fractures and dislocations treated nonoperatively or operatively to monitor for late instability and deformity. Should this occur, operative intervention is required.

**PULMONARY**

In patients with high cervical lesions, hypventilation may result from paralysis of the intercostal muscles and diaphragm. Hypoxia can ensue, requiring ventilatory support. Atelectasis and pneumonia are common causes of morbidity and mortality and must be treated aggressively.

Because patients with spinal cord injuries lose vasomotor tone and use of their upper and lower extremities, venous thrombosis and pulmonary embolism may be a problem. Emphasis should be placed on the prevention of venous thrombosis with compression pump stockings and other modalities. The use of prophylactic anticoagulants is controversial.

**GASTROINTESTINAL**

In his review of 300 patients with cervical spine injuries, Bohlin (7) found gastrointestinal hemorrhage to be a common problem. This occurred most commonly 10–14 days after injury and was highly associated with the use of steroids. Recovery in the groups treated with steroids did not differ from that in the group treated without steroids.

Other factors play a role in gastrointestinal complications, including excessive gastric secretions, gastric stasis, and immobilization of the patients. Prophylactic care, including H2 blockers, can be useful in the prevention of upper gastrointestinal hemorrhage.

**OPERATIVE**
Bacterial contamination in anterior or posterior operations can cause sepsis or wound infections, which may result in cervical osteomyelitis, meningitis, and death.

In anterior procedures, the esophagus can be injured by retraction or with instrumentation such as drill bits or screws. This may result in dysphagia, fistula formation, and infection.

An injury to the carotid artery can produce massive hemorrhage.

Do not use methylmethacrylate in fractures other than those of pathologic bone. Bone cement does not fuse with bone, and fixation loosens with time, resulting in instability. Increased infection rates have been associated with the use of cement.

Decompressive laminectomy for relief of anterior compression is usually not helpful and may cause increased neurologic deficit. Laminectomy can decrease stability and does not permit retrieval of anterior fragments from the canal. Because sublaminar wires take up space within the canal and can injure the spinal cord, they are contraindicated in cervical spinal trauma.

If reduction of a dislocation is performed when the patient is asleep, spinal cord monitoring may help detect the rare complication of retropropulsion of a ruptured disc causing spinal cord compression. If monitoring is not used, an intraoperative wake-up test may be performed. If there is a change in the neurologic status during or after a posterior procedure, perform anterior decompresion without delay.

Nonunion with the posterior triple-wiring technique within the C-3 to C-7 levels is rare. In a review of 100 consecutive patients, no nonunions or increased neural deficits were noted (52). Similar rates of fusion have been reported with anterior instrumented fusions (4, 33, 50).

BRACING

Patients who have neurologic deficits secondary to spinal cord injury must be followed for skin breakdown if they are placed in a two-poster orthosis or a halo jacket. Their insensate skin can break down easily. The two-poster orthosis and Philadelphia collar can cause breakdown over the chin region and therefore must be carefully applied and followed.

Potential complications of halo jackets are numerous. Pressure sores must be prevented. Pin placement and care are important when the ring is applied. Retorque the applied and followed.

Obtain radiographs periodically to assess the position of bone grafts and to look for loss of reduction. Before removing a halo jacket, obtain flexion and extension radiographs, after the connecting bars are loosened, to assess fusion and stability.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

To treat spinal column injuries properly, the physician must recognize life-threatening injuries and treat them appropriately, provide initial supportive care at the same time diagnostic studies are initiated, and protect the neural elements until definitive treatment can be provided. Whether acting in concert with a team of trauma specialists or alone in the emergency department, an orderly, stepwise approach to assessment and management will improve overall outcome and ensure that serious injuries are not missed.

In providing initial care to a spine-injured patient, the physician must perform the following procedures:

- Assess vital functions—airway, bleeding, circulation.
- Protect the spine while managing initial shock or life-threatening injuries.
- Initiate a diagnostic workup for suspected spinal injury.
- Stabilize the spinal column to protect the neural elements during further evaluation and any emergency procedures.

Once the patient is hemodynamically stable and the fracture is identified and classified, the surgeon can prepare a treatment plan based on the fracture pattern, the severity of injury, and the patient's overall condition.

INITIAL ASSESSMENT AND THE FUNDAMENTALS

In trauma management, the first priority is to preserve the patient's life. In some cases, the threat to life is evident (e.g., from hemorrhage, visceral trauma), but in others it is not.

Unstable thoracolumbar fractures are usually high-energy injuries. Anywhere from 40% to 80% result from motor vehicle accidents, involving drivers and passengers of automobiles, riders of motorcycles, and pedestrians (1, 7, 17, 18, 20, 23, 25, 29). Other causes of spine fractures include falls from height, penetrating trauma, and crush injuries, such as those sustained by a worker caught beneath a collapsing structure. In these kinds of injuries, polytrauma is common (Fig. 141.1). In our experience, patients with unstable thoracolumbar fractures suffer an average of two other major injuries in addition to their spinal fracture; some patients may present with as many as six associated injuries (20).

THE CHEST

Common injuries associated with thoracolumbar and thoracic fracture reflect the forces of blunt trauma and rapid deceleration. Intrathoracic injuries include the following:

- Pneumothorax and hemothorax associated with rib fractures or bronchial disruption
- Myocardial or pulmonary contusion
- Great vessel injury from blunt trauma or rapid deceleration
- Hemopericardium and cardiac tamponade
- Diaphragmatic rupture and acute hiatal hernia

Figure 141.1. Spinal trauma—a high-energy injury. A: Lateral radiograph of an 18-year-old man crushed under a wall, forced into extreme hyperflexion. He had massive thoracic injuries, a splenic laceration, and a progressive cauda equina injury. Radiograph demonstrates L-5 burst fracture. Pelvic radiographs also demonstrated bilateral sacral fractures—dislocations. B: CT scan shows comminuted lumbar fracture, with retropulsed vertebral body fragment abutting the volar surface of the laminae. C,D: AP and lateral radiographs after emergent stabilization and resuscitation. The patient underwent multiple procedures under the initial anesthetic, including splenectomy, chest tube placement, L-5 vertebrectomy, cauda equina decompression, posterior spinal stabilization L-4 to sacrum, placement of venous caval filter, and posterior stabilization of the pelvic disruption. This aggressive approach provided enough spinal column stability to allow early mobilization and aggressive pulmonary toilet. Four years after this massive injury, the patient was ambulatory with an ankle–foot orthosis, had mild back pain, and had returned to college.
A plain chest radiograph will confirm the presence of a hemothorax or a diaphragmatic rupture, and it may show widening of the mediastinum associated with a great- vessel injury. If multiple rib fractures are seen, particularly first rib and clavicle fractures, consider getting an angiogram to study the aortic arch.

Tension pneumothorax can be rapidly fatal, as can cardiac tamponade. Rapid placement of a chest tube will resolve the pneumo- or hemothorax, with immediate improvement of oxygenation and cardiac output. Pericardiocentesis will decompress the cardiac tamponade with rapid improvement in circulatory function. These injuries are often associated with thoracic fractures and fracture–dislocations. A quick assessment of bilateral breath sounds and heart sounds should identify either problem promptly. In a tension pneumothorax, breath sounds are absent or diminished on the injured side, and the esophagus and trachea are displaced toward the normal lung. In cardiac tamponade, there are indistinct heart sounds, and the neck veins are distended. Cardiac output is impaired in either case, and the patient manifests signs of shock and cyanosis.

THE ABDOMEN
Pay particular attention to patients with seat-belt injuries. The association of lap-belt abrasions with the classic flexion–distraction fracture should alert the physician to a high likelihood of intra-abdominal injury (12). Because this fracture occurs as the body is flexed forward over the lap-belt, visceral injuries are found in 40% to 60% of patients (10–27). Solid viscera may be injured directly when they are compressed between the body wall and the lap-belt, or they may be torn from their attachments when the body is suddenly and rapidly decelerated. Hollow viscera may be ruptured, perforated, or torn from their mesenteries. Obtain a general surgical assessment whenever a flexion–distraction injury is suspected. A rigid abdomen, falling hematocrit, and abdominal pain or tenderness are clear indications for emergent peritoneal lavage and laparotomy. In the stable patient with no symptoms of shock, an abdominal computed tomography (CT) scan may be used to rule out an abdominal injury. Intra-abdominal injuries are also common in thoracolumbar injuries.

THE EXTREMITIES
Because most unstable thoracic and thoracolumbar fractures are high-energy injuries, it is not surprising that they are commonly associated with additional skeletal injuries:

- Fractures of the femur, tibia, and feet are common.
- Fractures of the humeri and forearm bones are less common.
- Major pelvic fractures are not common and are usually seen only after massive trauma.
- Hemorrhage from multiple long-bone fractures can be severe, resulting in shock (3).

THE HEAD AND NECK
Injuries to the head and neck should be carefully assessed in the emergency room, and the cervical spine should be protected throughout the initial evaluation and emergency procedures (19). Uncoupsed, obtunded, or intoxicated patients cannot provide a dependable history or reliably report pain or numbness. These patients should be protected as though a cervical injury existed (2, 24). Plain radiographs will demonstrate the majority of bony injuries but may not reveal soft-tissue disruptions; retropharyngeal hematoma indicates significant soft-tissue injury and mandates a formal cervical workup (30). Head injuries may be evaluated by a magnetic resonance imaging (MRI) or CT scan prior to anesthesia if surgery is needed, or they may be held under observation if otherwise stable.

SHOCK
Shock may be seen for a variety of reasons. Hemorrhagic, hypovolemic shock is the most serious, and it must be recognized and corrected quickly. Young patients manifest tachycardia and peripheral vasodilatation as primary symptoms; hypotension may not be seen until shock is severe and vascular collapse occurs. Older patients generally do not compensate well, and tachycardia and hypotension may both appear early on.

- Place a Foley catheter to monitor urine output.
- Rapidly assess common sites of blood loss—open wounds, intra-abdominal and intrathoracic hemorrhage, and long-bone and pelvic fractures.
- Institute fluid resuscitation immediately.

Neurogenic shock results from loss of normal vasomotor tone. Patients present with hypotension and tachycardia although they have warm, well-perfused skin and peripheral tissues. They may not respond to fluid bolus, and vasopressors may be needed.

Shock may result from any condition that reduces cardiac output, including cardiac tamponade, tension pneumothorax, myocardial injury, or myocardial infarction. In every case, rapid vascular access and fluid resuscitation are the vital initial treatments for spinal trauma patients.

PROTECTING THE PATIENT
Once the potentially life-threatening injuries have been addressed or ruled out, the next priority is to stabilize and protect the patient's spine so that a more formal evaluation and workup can be carried out without injuring the spinal cord. This is particularly important in the polytrauma patient who may be unconscious, may require immediate ventilatory assistance, and must be immobilized in the prone position to prevent injury. Plain radiographs of the cervical spine are mandatory before intubating the patient, and if injury is seen or suspected, a fiberoptic nasotracheal intubation is the safest.

Transfer of the patient is safest on a spine board or slide board, and it should always be done with sufficient personnel to make the transfer smoothly and without struggling. When log-rolling the patient, the team must coordinate efforts to see that the shoulders and pelvis move together as a unit. If the patient is hemodynamically stable and does not require emergency procedures, he may be transferred to a firm mattress and maintained under strict spinal precautions until the workup is completed. Precautions include strict supine positioning, log-rolling side to side every 2 hours for skin care, and periodic reexamination of neurologic status.

INITIAL SPINAL EVALUATION
With the patient hemodynamically and mechanically stabilized, return to the spinal injury assessment. Obtain a complete history, paying close attention to reports of transient paresthesias, acute back or neck pain, or temporary weakness or paralysis at the time of injury. Record the location and radiation of pain symptoms, as well as any radicular symptoms. Any history of previous injury, fracture, or pain should be explored in detail. A global examination of motor and sensory function should rapidly focus on any areas of deficit. If the patient cannot cooperate with the exam, carefully observe and note spontaneous movements and withdrawal responses. Carry out a rectal exam to assess rectal tone, voluntary rectal control, and the bulbocavernous reflex. If the patient is neurologically normal, log-roll him to one side so that the spine can be palpated for step-offs, tenderness, or kyphosis. Note the condition of the skin over the symptomatic area. If a neurologic deficit exists, obtain radiographs of the symptomatic level before the patient is moved.

If a spinal cord injury is identified, start the patient on high-dose steroids to attempt to facilitate recovery (4). Steroids have been shown to improve spinal cord recovery relative to placebo and naloxone therapy, and they are thought to combat abnormal biochemical processes brought on by thromboxanes and prostaglandins released at the site of injury. Steroids must be given within 8 hours of injury to have any beneficial effect. Patients treated with high-dose steroids may be exposed to an increased infection rate and risk of gastrointestinal hemorrhage.

DIAGNOSTIC WORKUP
A formal physical examination and history may not be possible until the patient has been stabilized hemodynamically and has recovered from initial resuscitation. When the patient is alert and cooperative, a formal motor, sensory, and reflex examination should be repeated, and a detailed history of the accident obtained.

The history should focus on three issues: mechanism of injury; presence or absence of neurologic symptoms, and past history of spinal trauma, surgery, or symptoms. In high-energy injuries, it is often difficult to determine exactly what forces acted on the spine to produce fracture, but knowledge of the injury mechanism can help identify associated injuries and provide clues to the level of instability to be expected. A lap-belted patient in a motor vehicle accident may present with a straightforward flexion–distraction injury, for instance, whereas a patient ejected from the vehicle or from a motorcycle frequently will present with a more complex fracture pattern consistent with the combination of torsional and axial loading forces experienced when striking the ground. If the forces involved in the fracture were straightforward flexion–distraction injury, for instance, whereas a patient ejected from the vehicle or from a motorcycle frequently will present with a more complex fracture pattern consistent with the combination of torsional and axial loading forces experienced when striking the ground. If the forces involved in the fracture were straightforward flexion–distraction injury, for instance, whereas a patient ejected from the vehicle or from a motorcycle frequently will present with a more complex fracture pattern consistent with the combination of torsional and axial loading forces experienced when striking the ground.
recumbency to the patient’s life must be considered in timing a surgical procedure.

If the patient can recall the event, it is important to elicit any history of transient paresthesias or paralysis from the time of injury. Even if the patient’s symptoms resolved quickly, they suggest that some level of root or cord injury occurred at the time of the injury; therefore, assume that the spinal fracture is unstable. If the patient cannot give the details of the event, careful scrutiny of field notes can provide important clues to whether the patient had abnormal findings at the accident site. These notes are often gross evaluations only, however, and a patient with a severe cauda equina injury can still “move all four extremities.”

A history of previous trauma, surgery, or symptoms is important to understanding the current injury. Lower extremity weakness due to old injury or spinal disease can confuse the diagnostic picture after an acute injury, and a preexisting deformity—compression fracture, spondylolisthesis, or kyphosis—can be difficult to differentiate from a new injury. Furthermore, the surgical approach to the multiply operated back will be more demanding and may require different instrumentation than for an ordinary fracture.

The physical examination for the spinal-injured patient centers around a careful, complete neurologic assessment. Having examined the musculoskeletal system in the emergency department, carefully reexamine the extremities for tenderness and pain, and examine the back again to determine the level of discomfort and the presence of step-offs or gaps between the spinous processes, and to assess the skin over the area of injury.

Document a complete motor and sensory examination. Test each motor group for the lumbar and sacral plexuses independently and compare to the contralateral group (Fig. 141.2). Motor strength is recorded on a six-point scale:

**Fig. 141.2. Motor testing.**

5 full strength adequate to powerfully resist the examiner
4 power to resist but not overcome the examiner
3 power to overcome gravity
2 power to move the joint but not to overcome gravity
1 capacity to contract the muscle without functional power
0 no motor function at all

When extremity injuries are present, make an educated assessment as to whether the patient is clinically weak or limited in effort by pain. Also determine whether the pattern of weakness is consistent with a cord lesion, a root lesion, or a peripheral nerve injury.

The sensory examination begins at the chest wall and seeks a level of anesthesia, root by root, down to the sacrum. Patients with thoracic cord injuries will have an anesthetic level at or just below their fracture. If the anesthetic level and the recognized fracture do not coincide, obtain an MRI to determine the actual cause of the cord impairment. Sensation in the lower extremities follows a dermatomal pattern; test each dermatome for light-touch and pin-prick sensation (Fig. 141.3).

**Fig. 141.3. Dermatomal patterns.**

Check reflexes at both the knees and the ankles. The bulbocavernosus reflex, an involuntary contraction of the rectal sphincter, can be triggered either by gently squeezing the glans penis or glans clitoris or by gently tugging on the Foley catheter. If this reflex is absent, the patient either is in spinal shock or has suffered an injury to the caudal segments of the conus medullaris. Hyperactive reflexes suggest disinhibition due to a cord-level injury. Absent reflexes in an isolated distribution suggest an incomplete injury or root lesion. Complete absence of reflexes may be due to either spinal cord shock or a complete cauda equina injury. Spinal cord shock occurs at the time of injury and may persist for 72 hours. While the patient is in spinal cord shock, the neurologic examination remains unreliable—an incomplete injury may appear complete due to the overriding effects of cord shock. Once shock resolves and caudal reflexes return, the examination provides clear prognostic information: Incomplete injuries have potential for improvement, complete injuries have almost none. The bulbocavernous reflex is the most reliable level for testing reflex return because it tests the most caudal segment of the spinal cord.

The rectal examination deserves special comment. The most caudal motor and sensory unit in the body is the rectum, the function of which is crucial to independent social activity. Carry out an independent examination of rectal tone, sensation, and reflex activity. Do not rely on emergency department records if there is any concern of neurologic injury. Explain the purpose of the examination to the patient, who may be anxious over repeated exams. Document resting tone, voluntary contraction, perianal sensation, and bulbocavernous reflex.

Plain radiographs should include anteroposterior (AP) and lateral views of the thoracic spine and/or the lumbosacral spine, depending on the symptomatic level (18). On occasion, standard thoracic films will cut off T12–L1, and lumbosacral films will start at L1, giving an inadequate view of the most frequently injured level. If fracture of the thoracolumbar junction is suspected, repeat AP and lateral radiographs, centered at the T-12 level. In stable fractures (compression fractures, mild burst fractures, and mild flexion-distraction injuries), plain radiographs are sufficient to allow definitive treatment, and no further diagnostic studies are needed. In unstable spine fractures, however, additional imaging studies are often indicated.

Unstable fractures (severe burst fractures, fracture-dislocations, significant flexion-distraction injuries, and any fracture with a neurologic deficit) require further study to assess the extent of bony disruption, spinal cord impingement, canal compromise, and/or cord injury. A CT scan provides the most definitive information on bony characteristics, such as fracture pattern and comminution (8,11,15). The axial cuts of the CT scan can completely miss flexion-distraction injuries, however. An MRI is superior for soft-tissue details such as cord injury, cord compression, disc herniation, and ligamentous disruption (28). The MRI has the added benefit of scanning the entire thoracolumbar spine, and it can pick up noncontiguous fractures, cord injury, and epidural hematoma at levels other than that of the primary fracture. Longitudinal MRI cuts show the soft-tissue disruption and bony separation of flexion-distraction injuries well.

Myelography, the gold standard for assessing neural compromise just a decade ago, is now replaced by the MRI in all but a few cases. When an MRI is contraindicated
(e.g., intraocular fragments, cardiac valves), CT myelography is an appropriate but more invasive alternative.

There are two absolute indications for ordering MRI or myelography in the acutely injured patient:

- Any patient with a progressive neurologic deficit needs emergent imaging.
- Any patient whose neurologic level does not coincide with the recognized injury needs further evaluation for an unrecognized fracture or disc disruption.

Plain tomography is sometimes useful for evaluating the cervicothoracic junction when a CT scan cannot be obtained immediately. Flexion–extension studies or nuclear medicine scans have little role in acute trauma. There is no role for electrodiagnostic testing in the acute management of spine trauma patients.

FRACTURE CLASSIFICATIONS

Once the diagnostic evaluation is complete, the fracture can usually be classified according to one of a number of schemes. Holdsworth first characterized spinal fractures according to a two-column—anterrior and posterior—model of the spinal column (13,14). This model has since given way to the three-column model of Denis, which considers the vertebral body, anulus, and posterior longitudinal ligament to be the middle column, a discrete unit separate from the anterior and posterior stabilizers (5,6,22) (Fig. 141.4).

![Figure 141.4. Three-column model of Denis. A: Anterior column. B: Middle column. C: Posterior column.](image)

The first consideration is whether to classify a specific injury as stable or unstable. Unstable injuries include all those with any of the following:

- Three-column disruption
- Greater than 50% collapse of anterior cortex
- Greater than 25° of focal kyphosis
- Any extent of neurologic deficit

Although all stable injuries may be treated nonoperatively, not all unstable injuries need to be treated operatively. A simple algorithm for treatment is indicated in Fig. 141.5.

![Figure 141.5. Treatment algorithm for thoracolumbar fractures.](image)

After assessing the level of instability, classify the fracture according to fracture type and severity. The Denis fracture classification (Table 141.1) depends on information about the fracture pattern, the mechanism of injury, and the deforming forces that caused the fracture. The differences between severe burst fractures and rotational fracture–dislocations, and severe seat-belt injuries and flexion–distraction fracture–dislocations are subtle, and of limited importance: These severe injuries are all clearly unstable, and all require operative treatment.

![Table 141.1. Denis Fracture Classification](image)

COMPRESSION FRACTURES

Compression fractures are common injuries, occurring with moderate trauma in young patients and minimal to no trauma in elderly, osteoporotic patients. The anterior column collapses under an axial or flexion load, with fracture of one or both endplates, but the middle and posterior columns are undamaged. These stable injuries are appropriately treated with a removable brace and symptomatic care. Observe patients with advanced osteoporosis for progressive collapse; severe compression fractures may warrant a CT examination to rule out a burst component.

BURST FRACTURES
Burst fractures occur when the vertebral body is exposed to higher axial or flexural loads at a high loading rate. These fractures are commonly the result of motor vehicle accidents, falls from height, or crush injuries. The anterior cortex fails in compression, and either one or both endplates are fractured. The middle column is also fractured, and a portion of the posterior vertebral body is retropulsed backward into the canal. Depending on the severity of the fracture, the posterior elements may be fractured as well. Determine the need for surgical treatment by the extent of vertebral comminution, the extent of canal compromise, and the status of the posterior column structures (21). Burst fractures may be subdivided by fracture pattern:

- **Type A** fractures occur with axial loading, with fractures of both upper and lower endplates.
- **Type B** fractures are the most common (50%), with fracture of only the upper endplate.
- **Type C** fractures, with disruption of the lower endplate, are uncommon.
- **Type D** fractures have a rotational displacement of one body relative to the other on AP radiographs.
- **Type E** fractures are lateral compression injuries, with traumatic scoliosis (Fig. 141.6).

**Figure 141.6.** Burst fracture patterns.

Canal compromise is most accurately assessed on a CT scan, by comparing the AP diameter of the normal spinal canal at an adjacent level to the reduced diameter at the level of the retropulsed fragment (26). The ratio of the injured to the intact diameters provides the percent compromise (Fig. 141.7). The greatest compromise occurs at the level of the pedicles and upper vertebral body. In type A and B burst fractures, the central portion of the posterior cortex and body is driven back into the canal between the two pedicles, which then prevent the fragment from reducing. Because of the differing volumes of neural tissue in the canal at different levels, compromise of greater than 50% may produce symptoms at the thoracolumbar junction, whereas compromise of 85% or more may be well tolerated at the lumbosacral junction (9). A CT scan will also demonstrate the presence and extent of posterior element disruptions (Fig. 141.8). Three-column injuries are inherently more unstable than two-column injuries, and the inability to load the posterior facet joints in a hyperextension cast may exclude nonoperative care for some patients.

**Figure 141.7.** Canal dimension at injured level (A) is compared to adjacent normal level (B) to determine percent canal compromise.

**Figure 141.8.** Radiographic characteristics of burst fractures. **A:** Lateral view demonstrates fracture of anterior cortex and superior endplate, with resulting focal kyphosis. The posterosuperior portion of the vertebral body can be seen retropulsed into the spinal canal, with loss of normal concave contour of the posterior vertebral body. **B:** AP radiograph demonstrates the increased intrapedicular distance associated with a burst fracture; the distance between the L-1 pedicles is significantly greater than for the levels either above or below, indicating a complete disruption of anterior, middle, and posterior columns.

**FLEXION-DISTRACTION FRACTURES**

Flexion-distraction, or seat-belt fractures may be either one- or two-level injuries (5, 10, 12, 27). The classic one-level injury is the Chance fracture. The mechanism of injury involves the patient being thrown forward across an intact lap-belt, resulting in a hyperflexion force acting around a center of rotation anterior to the spinal column—at the belt itself. This results in distraction forces at all three columns of the spine: (a) The posterior elements are torn apart through either the facet joints or the bone itself, (b) the middle column is torn apart through either the posterior disc or the posterior vertebral body, and (c) the anterior column is either disrupted (in severe injuries) or left as a hinge that cannot resist either flexion or rotational displacement. Plain radiographs demonstrate the gap between the spinous processes and the disruption of the pedicle in most cases (Fig. 141.9) but may show minimal displacement when the patient is supine because the fracture tends to reduce in this position. An MRI shows the injury clearly.
The violent compression of viscera between the spinal column and lap belt can rupture hollow viscera, lacerate solid viscera (liver and spleen), and avulse major vascular pedicles. Unrecognized, any of these injuries can prove rapidly fatal; it is therefore necessary that any patient with a seat-belt injury be carefully assessed by a general surgeon for acute or occult intra-abdominal injury.

Single-level injuries pass through the posterior ligamentous structures and the underlying disc at the same level, or through the posterior lamina, pedicle, and vertebral body in the same transverse plane (Fig. 141.10). These injuries disrupt only a single motion segment. Two-level injuries begin posteriorly at one level of lamina or facet joint, then proceed anteriorly in an oblique fashion so that the injury passes out of the vertebral body into an adjacent disc or through the disc into an adjacent body. In these injuries, two adjacent motion segments are disrupted, and stabilization requires addressing both levels of injury.

Fracture–dislocations are, by definition, three-column injuries. They are highly unstable, usually associated with neurologic injury, and often associated with other musculoskeletal and visceral injuries. The neurologically intact patient must be carefully protected during any necessary testing or emergent operative procedures, and the spine must be stabilized at the first reasonable opportunity to allow mobilization and prevent paralysis. In the patient with neurologic deficit, postural reduction may improve alignment and reduce neural compression, and longitudinal traction may allow manual reduction of a displaced fracture–dislocation. Neither will reduce neural compression by retroplused vertebral fragments, however, and direct decompression is indicated for those patients with an incomplete injury and hopes of improvement.

Flexion–rotation fracture–dislocations (Fig. 141.11) are caused by hyperflexion and rotation forces such as seen when a patient is ejected from a vehicle at high speed. When the vertebral body is fractured, this injury may be indistinguishable from a severe type D burst fracture. Shear fractures are more uncommon injuries and occur in the absence of axial loading or flexion–extension forces. Translational forces occurring when the subject is struck squarely from the side, front, or back act to shift one vertebral body relative to the next by shearing through bony articulations and ligamentous structures. Flexion–distraction fracture–dislocations occur when all three columns fail in hyperflexion. These injuries are often not distinguishable from severe seat-belt injuries.

A key consideration in fracture–dislocations is that all three columns are unstable in both axial loading and in longitudinal traction. Instrumentation systems that depend on distraction forces to secure hook purchase cannot be safely applied in these injuries, and any system incorrectly applied may overdistract the fracture and stretch the neurologic elements, precipitating or worsening the neurologic injury.

**AUTHORS’ PERSPECTIVE**

Successful fracture treatment begins with a careful and comprehensive initial evaluation. The key to success is, as always, to look at the whole patient—never allowing a single, dramatic injury to distract attention from more subtle, and potentially more dangerous, injuries. Once the patient is hemodynamically stable, and the fracture is recognized and classified, prepare a treatment plan based on the fracture pattern, the severity of injury, and the patient’s overall condition. The options for nonoperative and operative treatment are extensive, and the correct choice for any patient must be determined by weighing all the above considerations, as well as the surgeon’s experience, against the potential risks of treatment.

INTRODUCTION

Since the early 1980s, operative treatment has moved to the forefront of fracture management in the spine. Techniques and implants have evolved to provide better results with decreased morbidity and mortality (1,9,13,17), and current operative management more rapidly returns the patient to work and satisfactory function (9,10,20,86). Changes in health care management and patient expectations have made prolonged bed rest or immobilization unacceptable (12). Improved imaging, a better understanding of fracture and implant biomechanics, and the introduction of a variety of new anterior and posterior fixation devices allow surgeons to plan definitive stabilizing procedures for any fracture pattern, allowing rapid mobilization and return to function. Hence, patients who cannot be mobilized in a cast or brace within a few days of their injury are often more reasonably treated with surgery.

The goals of treatment, operative or otherwise, remain to

1. Protect neural elements, restore/maintain neurological function;
2. Prevent or correct segmental collapse and deformity;
3. Prevent spinal instability and pain;
4. Permit early ambulation and return to function; and
5. Restore normal spinal mechanics.

NONOPERATIVE TREATMENT

Only 20% to 30% of spine fractures require surgery. The rest can be treated nonoperatively in a brace, molded orthosis, or hyperextension cast. Single-column injuries (e.g., compression fracture, laminar fracture, spinous process fracture) are treated in an off-the-shelf brace that encourages normal spinal alignment and limits extreme motion (Fig. 142.1). More significant compression fractures may be treated in a molded orthosis. Two-column injuries, including severe compression fractures, mild to moderate burst fractures, and bony Chance fractures, are too unstable to be braced but may well be reduced and maintained at bed rest or in a hyperextension cast. Previous studies (6,8) have shown that even severe burst fractures can be treated with a regimen of bed rest, postural reduction, and casting. Bony remodeling reduces residual canal compromise by more than 50% over the course of a year (71) (Fig. 142.1), making surgical treatment unnecessary in many patients, including those with retropulsed fragments in the spinal canal. Recumbent treatment, although effective, is very expensive and rarely reimbursed or permitted in managed care systems.

Hyperextension casting, on the other hand, allows immediate mobilization and early return to independent function.

Figure 142.1. Fracture remodeling. A: Thoracic level burst fracture. With nonoperative treatment, normal remodeling mechanisms tend to restore canal diameter compromised by retropulsed bony fragments. B: Resorption of the retropulsed vertebral body results in a “heart-shaped” canal with near-normal anteroposterior (AP) diameter 1 year later. (Courtesy Joseph Mumford, MD, Topeka, KS.)

The hyperextension cast can be used in many patients with severe compression fractures or burst fractures. Figure 142.2 shows an example of closed reduction and casting for thoracolumbar fractures.
Axial or sagittal collapse can compromise neurologic elements, and anterior decompression and stabilization should be considered for both mechanical and neurologic compress segments within the construct to either decompress the fracture site or compress an anterior graft.

Figure 142.3. Patients with sagittal collapse tend to have more pain and may develop new neurologic symptoms if kyphosis progresses (Fig. 142.3). Thoracolumbar and lumbar fractures with severe collapse and vertebral comminution tend to lose correction over time unless anterior instability is corrected. (Fig. 142.3). The segmental fixation system allows multiple points of fixation, to distribute reduction forces more evenly. Posterior systems cannot resist sagittal deforming forces if the anterior spinal column is deficient, however (70). Thoracolumbar and lumbar fractures with severe collapse and vertebral comminution tend to lose correction over time unless anterior instability is corrected. Patients with sagittal collapse tend to have more pain and may develop new neurologic symptoms if kyphosis progresses (67-70).

INDICATIONS

COMPRESSION FRACTURES

Compression fractures are usually single-column injuries, are typically stable, and rarely cause neurologic injury. A hyperextension orthosis or chair-backed brace is sufficient to allow ambulation and return to limited activity. Braces and removable orthoses cannot generate the hyperextension forces necessary to maintain sagittal alignment and should not be considered substitutes for a well-molded hyperextension cast. Also see Chapter 10.

Operative treatment offers significant advantages over casting or recumbency (18,32,43,44,52,53). First, immediate spinal stability is provided for patients who can tolerate neither a cast or prolonged recumbency. Prolonged recumbency in multiply injured patients predisposes them to severe and life-threatening complications. Prompt surgical stabilization allows the patient to sit upright, transfer, and start rehabilitation earlier, with fewer complications (14,31,42). Second, surgical treatment more reliably restores sagittal alignment, translational deformities, and canal dimensions than does cast treatment. And, finally, surgical decompression more reliably restores neurologic function and decreases rehabilitation time (18,23,52,72).

BURST FRACTURES

Stable burst fractures (two-column injuries) may be treated in a hyperextension cast if the patient has no abdominal or thoracic injuries. Unstable injuries typically require operative reduction and stabilization.

- Burst fractures that are considered unstable include
  - Greater than 50% axial compression.
  - Greater than 20° angular deformity.
  - Multiple contiguous fractures.
  - Neurologic injury—complete, incomplete, or root.
  - Three-column injuries and dislocations.
  - Patients with extensive associated injuries.
  - Greater than 50% canal compromise at L-1 and 80% compromise at L-5.

Neurologically Intact

In patients with no neurologic injury, treatment decisions are based on issues of mechanical stability and sagittal alignment primarily, and canal compromise secondarily. In the thoracic region, sagittal deformities are corrected by longitudinal distraction, which may also indirectly reduce some retropulsed vertebral fragments from the spinal canal. In the lumbar region, forceful distraction tends to reduce lumbar lordosis, introducing sagittal imbalance and a flat back. Forceful distraction in a patient with a three-column injury may inadvertently lengthen the spinal column and stretch the spinal cord, causing neurologic injury. Segmental spinal systems now allow segmental distraction within the construct while neutralizing construct length and sagittal alignment (Fig. 142.3). The segmental fixation system allows multiple points of fixation, to distribute reduction forces more evenly. Posterior systems cannot resist sagittal deforming forces if the anterior spinal column is deficient, however (70). Thoracolumbar and lumbar fractures with severe collapse and vertebral comminution tend to lose correction over time unless anterior instability is corrected. Patients with sagittal collapse tend to have more pain and may develop new neurologic symptoms if kyphosis progresses (67-70).

Canal compromise should be assessed in every burst fracture, but it becomes the primary concern only when a high degree of compromise is recognized. Residual compromise greater than 50% is worrisome at the T12-L1 level, where the conus medullaris and cauda equina fill the spinal canal (Fig. 142.4). Small increments of axial or sagittal collapse can compromise neurologic elements, and anterior decompression and stabilization should be considered for both mechanical and neurologic

Figure 142.2. Closed reduction and hyperextension casting of thoracolumbar fractures.

- Place the patient on a modified fracture table (Fig. 142.2A). Suspend the patient on a narrow, midline, taut canvas support in cervical halter traction, with arms out to the side, knees flexed, and feet resting on the support to give the patient a sense of balance.
  - Apply a vertically directed force that will achieve hyperextension at the fracture site (Fig. 142.2B). Once maximum hyperextension is achieved through this means, relax the horizontal canvas support and place additional traction on the iliac crests.
  - After satisfactorily positioning the patient on the table, wrap the torso with Webbril (Fig. 142.2C). Pad the bony prominences additionally with foam and apply the cast.
  - Note the extreme hyperextension placed into the cast, as well as the large anterior abdominal hole that has been created (Fig. 142.2D, Fig. 142.2E). Send the patient to the x-ray department for postreduction and casting x-ray studies. If satisfactory alignment has been achieved, allow the patient to ambulate immediately.

If the posterior elements are intact, axial loads are transferred posteriorly through the facet joints, allowing immediate weight bearing and good restoration of sagittal alignment and vertebral body height. In Chance fractures, hyperextension closes the posterior defect and approximates the fracture margins. The cast cannot be placed until the abdomen is cleared and any ileus or distention has subsided, however, limiting its use in polytrauma patients. Patients with abdominal trauma, prolonged ileus, chest trauma, or multiple extremity fractures may not be suitable for casting for some time after admission. Once the abdomen is cleared and a well-molded cast is applied, the patient may begin transfers and ambulation. Braces and removable orthoses cannot generate the hyperextension forces necessary to maintain sagittal alignment and should not be considered substitutes for a well-molded hyperextension cast. Also see Chapter 10.
Fracture-dislocations are the result of high-energy trauma (motor vehicle accidents and falls from height) and are typically associated with severe neurologic damage. More aggressive surgical approach. Pedicle instrumentation or extended segmental constructs are often needed to stabilize these fractures. Three-column flexion-distraction injuries are highly unstable. The incidence of spinal cord injury is high, as is the incidence of intra-abdominal injury, necessitating a more aggressive surgical approach. Pedicle instrumentation or extended segmental constructs are often needed to stabilize these fractures. Neurologically Compromised

In patients with a neurologic injury, operative treatment is carried out to protect residual function, restore neurologic deficits, and allow early mobilization and rehabilitation without a cast. If the cord or cauda equina injury is incomplete, neurologic decompression can significantly improve the eventual outcome. Assuming that there is significant residual compression at the time of surgery, if no residual compression exists, posterior stabilization is carried out alone. If the neurologic injury is complete, anterior surgery will not improve the chance of neurological improvement but may be indicated to treat sagittal deformity or instability. Posterior instrumentation is usually adequate to allow immediate transfers and early rehabilitation.

Flexion-distraction injuries may occur through bone or soft tissue, and may involve one or multiple motion segments. Two-column injuries occurring through bone heal reliably and may well be treated in a hyperextension cast. Ligamentous injuries do not heal reliably and more often result in residual instability and pain. These injuries are best treated with a short compression construct and posterior fusion, as are patients with abdominal injuries in patients who cannot tolerate a cast. Three-column flexion-distraction injuries are highly unstable. The incidence of spinal cord injury is high, as is the incidence of intra-abdominal injury, necessitating a more aggressive surgical approach. Pedicle instrumentation or extended segmental constructs are often needed to stabilize these fractures. Fracture-dislocations are the result of high-energy trauma (motor vehicle accidents and falls from height) and are typically associated with severe neurologic damage.
and multiple associated injuries (67,74,75). Complete spinal cord lesions do not improve with surgery, but mortality and morbidity are both improved by early mobilization and rehabilitation. Cauda equina lesions are less predictable than thoracic lesions (some improvement may be seen), and restoration of spinal alignment is indicated to stabilize the spine and to decompress entrapped and compressed roots.

**SURGICAL TIMING**

The patient's overall condition must be considered in making a surgical decision. Delaying treatment affords no benefit to the patient but may allow the surgeon to assemble a more skilled team of personnel. If the patient is stable, neurologically intact, and not suffering from multiple injuries, it is safe and reasonable to schedule surgery for the next elective opportunity. On the other hand, morbidity or mortality are not increased by taking the patient to the operating room on an emergent basis, and in some instances, an emergent stabilization may prove instrumental in the patient's overall management.

Patients with thoracic fracture-dislocation associated with severe chest trauma and pulmonary contusion may deteriorate rapidly after hospitalization. Recumbency frequently leads to hypoventilation, pneumonia, and sepsis, irrespective of antibiotic prophylaxis, making delayed stabilization impossible. Pneumonia and respiratory insufficiency will not clear until the patient can be set upright, so a vicious circle is initiated that may take weeks to resolve or may even take the patient's life. Early stabilization (12 to 24 hours) allows aggressive pulmonary toilet, upright positioning, and limits time on the ventilator and in the intensive care unit (ICU), reducing the likelihood of nosocomial infection. Indications for urgent or emergent stabilization include:

- Severe chest trauma, pulmonary contusion.
- Polytrauma, with multiple injured systems or long-bone fractures.
- Progressive neurologic deficit.
- Fracture dislocation in a patient already undergoing emergency surgery.
- Fracture dislocation or deformity threatening skin breakdown.

In a recent review of polytraumatized spine fracture patients, perioperative and postoperative morbidity were not increased by emergent stabilization, but neurologic improvement was increased and life-threatening complications were reduced (77a) (Table 142.1). Note that overall mortality is this study was significantly less predicted by the high Injury Severity Score (ISS), where an ISS of greater than 40 typically results in a 50% mortality rate in this age group.

**INSTRUMENTATION OPTIONS**

Because the decision to operate is usually predicated on the presence of spinal instability, instrumentation is almost always incorporated into the surgical plan. The type of instrumentation used depends on the injured level, the fracture pattern, the need for anterior stabilization or decompression, and the surgeon's level of experience and training.

Options for instrumentation include:

- Nonsegmental rod/hook systems (Harrington rod).
- Hybrid systems (Luque; Harrington rod with sublaminar wires).
- Segmental systems.
- Rod/hook constructs
- extended pedicle screw constructs
- short-segment pedicle instrumentation (SSPI)
- compression instrumentation
- anterior screw/plate or screw/rod instrumentation

**HARRINGTON RODS**

Harrington rods have been largely replaced by segmental spinal systems but can still play a role in fracture stabilization, primarily in the thoracic spine. Applied properly, Harrington distraction rods can reduce angular deformity, restore vertebral body height, and provide adequate stiffness to allow early mobilization (6,41,52-54). Fixation is dependent on strong distraction forces between the superior and inferior hooks, however, and constructs must span a number of vertebrae to provide optimal corrective forces. Constructs that span three levels above and two below the injury are biomechanically superior to shorter constructs. Three-column spinal injuries cannot resist the distraction forces of the Harrington rod, however, and rods placed in these injuries will either overdistort the spinal column or will not be firmly fixed.

Harrington rods also break in 7% to 10% of cases, usually at the junction of the ratchet and the main rod body (60). Because there are only two points of fixation on each rod, forces tend to concentrate at those points, and lamina fracture or hook dislodgement are frequent, leading to complete loss of fixation (52,56-60).

**HYBRID CONSTRUCTS**

Adding sublaminar or spinous process wires significantly improves fixation of the Harrington rod and limits the risk of hook displacement (55). Spinous process wires are less likely to pull sublaminar hooks into the canal, but well-fitted hooks are unlikely to displace with either technique (Fig. 142.7). These constructs are best suited to fractures of the midthoracic spine, where extended fusions are relatively well tolerated. Although the addition of sublaminar segmental wires has improved the sagittal and torsional stiffness of Harrington constructs (3,19,63,81,85), it has not eliminated rod breakage. Luque instrumentation may prove useful in some thoracic fractures but does not provide sufficient axial stability to treat burst fractures.

**Figure 142.7. Harrington rod fixation for thoracic fractures. Harrington rods, supplemented with sublaminar wires (A) or interspinous wires (B), provide sufficient rigidity.**
and stability to treat many thoracic level fractures and fracture dislocations.

SEGMENTAL SPINAL INSTRUMENTATION

Segmental spinal instrumentation has improved treatment results for a variety of spinal disorders. Originally intended for scoliosis patients, segmental hook and rod systems have now been used to successfully treat trauma, infections, tumors, and degenerative disorders (51,59,70). Clinical series have documented the efficacy and technical demands of segmental systems in scoliosis, kyphosis, and congenital deformities, and have provided the clinician with enough information to develop rational and reliable treatment plans. Such principles have not been as well established for fracture treatment, however.

Segmental instrumentation is being used with increasing frequency for thoracic and thoracolumbar spine fractures, but only a handful of clinical studies have been published to support this application (47,64,80). McBride reported good results in thoracic and thoracolumbar fractures treated with longer hook and rod constructs (54,56), and SSPI constructs have been endorsed for treatment of lumbar fractures (7,69). Enthusiasm for SSPI has been tempered somewhat by recent studies identifying a high rate of screw failure in unstable fractures (4,8,68,70), however.

Segmental rod/hook constructs take advantage of three-point bending mechanics to reduce and maintain thoracic kyphosis and prevent translation of disrupted vertebral segments. The success of this strategy has been documented in nonsegmental systems (Harrington rods), and a number of construct patterns have been presented for segmental systems (64,65,80). Although they use the same basic reduction strategy as the Harrington rod, segmental rod/hook systems offer several unique advantages over first-generation instrumentation systems (6,39,49):

- Proximal and distal hook pairs (claws) provide more stable fixation than the Harrington hooks they replaced.
- Segmental systems are not dependent on strong distraction forces for purchase.
- Contact between the rod and the lamina still provides correcting forces in the sagittal plane.
- Segmental systems allow placement of intermediate hooks, thus distributing corrective forces over more laminae and reducing the likelihood of hook pull-out or fixation failure.
- Segmental constructs are stiffer than Harrington rods in both axial and torsional loading.

PEDIQUE SCREW FIXATION

Pedicle screws allow the surgeon to instrument vertebras with absent or fractured laminae directly. They provide three-column fixation in unstable injuries and limit the length of fusion in the lumbar spine (50). Pedicle screws may be used exclusively or in combination with hook constructs to address a wide variety of fracture patterns. Combined (or "extended") constructs are particularly useful at the thoracolumbar junction. Here, the thoracic spine is relatively immobile and tolerant of fusion.

Extending the construct into these segments incurs little mechanical cost and provides more extensive fixation. This improved proximal fixation allows the surgeon to apply enough corrective force to restore sagittal alignment, an imperative at the thoracolumbar junction. Pedicle screws are then applied in the upper lumbar segment to limit the length of the construct, minimizing interference with lumbar motion segments. Extending fusion into the lower lumbar spine does alter mechanics and predisposes patients to junctional pain and subsequent degeneration.

The extended construct often incorporates an intermediate hook applied just above the fracture and just below the upper claw, and directed either cranially or caudally, depending on the situation. In most constructs, a narrow-width hook is placed up-going under the lamina of the vertebra two levels above the fracture. With the upper and lower fixation points locked in place to neutralize the construct length, this hook allows segmental distraction of the fracture to improve vertebral height and decompress the spinal canal indirectly without overdistracting the spine. In anterior and posterior reconstructions, this additional hook may be directed downward to compress and capture the anterior strut graft.

SSPI allows rigid fixation of short segments of the lumbar spine and provides sagittal, axial, and torsional stability superior to rod/hook constructs or sublaminar wiring (48,50). Fixation is not dependent on intact lamina, so there is no need to extend the fusion in cases of laminar fracture or laminectomy. Because distraction is not needed to correct the axial deformity, the risk of either overdistracting the disrupted segment or producing a flat-back syndrome is lessened. Both the surgical and mechanical disturbance to the adjacent lumbar segments is minimized. Nevertheless, SSPI is limited in its ability to maintain sagittal correction in severe burst fractures (7,69,70). If the anterior and middle spinal columns cannot share axial loads, the bending moments generated at the pedicle screw hub result in a high rate of bending failure or fracture. Once initial bending has occurred, progressive collapse is more likely, with progressive loss of lordosis in some patients.

ANTERI0R PLATES AND SCREWS

A number of anterior fixation systems have been developed over the past 10 years, all based on the principle of anterolateral screw fixation coupled with longitudinal plates or rods (Fig. 142.8). These devices can span multiple segments and can be applied from the midthoracic region down to the L-5 vertebral body. They are intended to augment anterior column reconstruction, providing torsional and translational stability while sharing axial loads with a strut graft or cage (see Chapter 137). When posterior soft tissues and structures are intact, an anterior reconstruction and instrumentation may be adequate to stabilize the spine. If the posterior elements are disrupted, however, the anterior construct is likely to fail unless posterior instrumentation is carried out as well.

Figure 142.8. Anterior instrumentation for burst fracture treatment.

SURGICAL TECHNIQUES

Instrumentation provides little benefit unless the spinal alignment is corrected at the time of fixation. Failure to correct sagittal alignment will result in a fixed kyphotic deformity, predisposing the patient to dysfunction, pain, and instrumentation failure, and necessitating late revision and reconstruction. Failure to correct translational deformity will result in a residual stenosis at the level of offset, and may predispose the patient to nonunion and treatment failure.

POSTURAL REDUCTION OF FRACTURE

The residual deformity in compression, burst, and many dislocation injuries is kyphosis. If this deformity is allowed to persist, it will become fixed and irreducible, but immediately after fracture, fragments are typically mobile and amenable to indirect reduction.

- If nonoperative treatment is planned, place the patient supine over a bolster until provisional healing has occurred (84) or until the patient is ready for casting. For operative care, accomplish reduction by properly positioning the patient on the surgical frame.
- Return fractures of the thoracic spine to normal kyphosis by placing the patient on a Wilson frame, adjusted to fit the patient's chest wall. Avoid hyperextension.
- Reduce fractures of the lower lumbar spine on either a Wilson or a fracture frame.
Carry out instrumentation of the shortest possible segment with the hips extended and the torso positioned comfortably on the frame of choice.

Fractures at the thoracolumbar junction are most problematic for the following reasons: (1) The injured segments are junctional between the rigid thoracic spine and the well-supported lumbosacral vertebrae. (2) The neural elements at risk include the conus medullaris and entire cauda equina. (3) Residual deformity is poorly tolerated, and mechanical imbalance predisposes the patient to pain and construct failure.

Position the patient gently and carefully in the prone position, with support under the iliac crests distally and the anterior chest wall proximally. Allow the abdomen and midtrunk to hang free.

Options for positioning include transverse bolsters, the Relton-Hall type frame, and the Jackson turning frame. The Jackson turning frame allows the surgeon to position bolsters, arm boards, and headrest with the patient supine and awake, then turn the frame and patient as a unit without further repositioning (Fig. 142.9). A Wilson frame attachment is also available.

**Figure 142.9.** Postural reduction of burst and flexion distraction injuries. Normal thoracolumbar lordosis can be restored by placing patient on a spinal frame supporting the torso and pelvis and allowing the abdomen to hang free. Further elevating the thighs will increase the lordosis in segments adjacent to the fracture, which helps in restoring normal alignment.

As the abdomen and lower torso hang free, normal lumbar lordosis is accentuated, reducing the kyphotic deformity.

Because postural reduction does not completely reduce the kyphosis of a severe burst fracture, it is incumbent on the physician to recognize residual deformity intraoperatively and manually restore thoracolumbar alignment at least to neutral position.

**OPEN REDUCTION OF FRACTURE**

To complete reduction of a burst fracture, it may be necessary to manipulate the spine operatively. Two options are available. First, in situ contouring of the implants can restore lordosis to segments that are not completely reduced passively.

- Contour standard rod and screw or plate and screw constructs in situ to restore sagittal balance, or contour the rod before placement and then insert and rotate it into sagittal orientation to increase lordosis. Take care not to overpower and damage the implants, however.
- Supplement pedicle screws by offset laminar hooks before attempting vigorous contouring.
- Implants designed specifically for fracture reduction are available; they are designed to neutralize construct length at the same time that manipulation of the pins corrects sagittal collapse (7, 30, 37, 38).

**Short-Segment Pedicle Instrumentation**

Correction of residual kyphosis is important in the thoracolumbar region. Transpedicular instrumentation systems limit the extent of the spinal fusion to a few levels, and allow direct reduction of deformity. **Figure 142.10** illustrates the use of SSPI:

- After obtaining the best postural reduction, place screws according to anatomic landmarks and fluoroscopic control (step A).
- Apply the fixation rod and carry out gentle axial distraction to restore the normal height and alignment of the posterior elements (step B).
- Restore lordosis by levering the dorsal extensions of the screws together to distract the anterior and middle columns back to their normal height (step C). The sagittal rotation force applied at the screw-rod connection will further lengthen the posterior column as well, so avoid overdistraction during step B.
- Then tighten the locking nuts to fix both the axial and the sagittal correction.

**Transpedicular Bone Graft**

The second option is to reduce the vertebral collapse directly through a posterolateral approach. Using this method, the surgeon elevates the depressed endplate through a transpedicular approach and reinforces the fracture site with a transpedicular bone graft (Fig. 142.11).
To restore the anterior weight-bearing column without strut–graft reconstruction, carry out a transpedicular reduction and grafting.

Using a specially designed instrumentation set (Synthes NA, Paoli, PA), directly elevate the fractured endplate using a transpedicular approach.

Impact fracture fragments into the fracture defect or remove them through a transpedicular decompression.

Impact additional graft, harvested from the pelvis using an acetabular reamer, into the anterior half of the vertebral body using a transpedicular funnel and stylet.

Irreducible facet dislocations may require an operative reduction to restore alignment. Fracture-dislocations are usually reduced easily because the soft tissues are completely disrupted. If part of the facet capsule or posterior longitudinal ligament is intact, manual reduction is more difficult. In such a case, in a neurologically intact patient, use a burr to take down the locked facet and allow a gentle reduction without overdistraction of the spine (Fig. 142.12).

**Figure 142.12.** Reduction of fracture-dislocation. When simple distraction cannot easily reduce a dislocated facet in a neurologically intact patient, resection of the overlapping articulation with a Kerrison rongeur or burr will allow gentle reduction.

**FUSION TECHNIQUE**

Because segmental instrumentation allows the surgeon to instrument only those segments intended for fusion, the routine practice is to fuse all instrumented segments. Long rod/short fusion constructs have been only marginally successful at protecting lumbar segments in fracture patients (3), and newer systems allow surgeons to avoid instrumenting the lower lumbar spine altogether. This technique eliminates the need for a second surgery to remove the hardware and avoids concerns over degenerative changes seen in immobilized, unfused facet joints (21,56).

- Observe meticulous fusion technique to avoid pseudarthrosis.
- After stabilizing the fractured segment, decontaminate laminae, and transverse processes, take down the facet joints, and liberally dress the lateral and dorsal surfaces with autologous iliac crest graft.
- Concentrate corticocancellous strips of autograft bone across the fractured segment and around the construct ends, which are typical areas of fusion failure.
- Take care to preserve the adjacent facet joints and avoid extending the fusion beyond the instrumented segments.

**STABILIZATION TECHNIQUES**

**Thoracic Spine**

- Stable thoracic compression and burst fractures may be treated in a Jewett brace or thoracolumbar sacral orthosis (TLSO) with good results.
- Multilevel compression or burst fractures will collapse into further kyphosis; instrument either with a Harrington rod and Drummond wires or with a segmental rod/hook construct. If the Harrington system is used, follow the old rule of “three above, two below,” with spinous process wires placed at each intact laminar level.
- Contour the rods to fit the thoracic kyphosis better but leave them somewhat straighter than the desired alignment to provide a third reduction force where the rod contacts the spinal laminae.

Segmental instrumentation can be placed in a variety of ways, depending on the fracture level and pattern.

- For compression fractures, place a simple transversopedicular claw (Fig. 142.13) above and below the fracture level.

**Figure 142.13.** Proximal fixation patterns. A: Proximal transversopedicular claw constructs mirror those applied in adult deformities. B: In osteoporotic bone, or when the transverse process has been broken, a laminolaminar claw can be substituted.

- In more severe fractures, use additional claws and intermediate hooks to provide secure fixation and allow intersegmental distraction.
- The rod/hook construct should take advantage of three-point bending mechanics to reduce and maintain thoracic kyphosis and prevent translation of disrupted vertebral segments.

The proximal and distal “claws” provide more stable fixation than the Harrington hooks they replace and are not dependent on strong distraction forces for fixation.

The additional hooks applied in segmental constructs distribute corrective forces over more laminae, reducing the likelihood of hook pull-out and fixation failure.

- Arrange hooks to accommodate the regional anatomy and the fracture pattern, as long as at least two hooks are applied on either side of the fracture (Fig. 142.14A, Fig. 142.14B, Fig. 142.14C and Fig. 142.14D).

**Figure 142.14.** Construct patterns for posterior instrumentation: Four basic construct patterns have been applied in thoracic, thoracolumbar, and lumbar...
fractures, with or without anterior reconstruction. A: Upper and lower hook patterns used primarily in the thoracic segments but sometimes in the thoracolumbar segments. These consist of claw configurations above and below the fractured level, with supplemental hooks applied as an additional claw above the fracture in lower thoracic fractures (1), below the fracture in upper thoracic fractures (2), and across the fracture in the midthoracic region (3). B: Extended pedicle screw patterns used at the thoracolumbar junction. Pedicle screws placed below the fractured level are supported by offset laminar hooks or additional screw fixation at the level below. Proximal fixation is provided by a claw construct carried to the lower thoracic segment. A supplemental hook is placed above the fracture, providing distraction against the lumbar screws when an indirect reduction is desired (1), and compressing the anterior graft when a direct decompression has been performed (2). C: Short-segment pedicle instrumentation (SSPI) patterns used in thoracolumbar and lumbar fractures to limit fusion. Specifically designed constructs are available, or SSPI constructs can be designed from standard instrumentation sets. If the anterior column is unstable, protect posterior screws with an anterior strut (1), or with offset hooks applied above and below the screws (2). D: Compression construct patterns. Flexion distraction injuries are generally treatable with a simple posterior compression construct (1). If a fracture dislocation has occurred, pedicle screw instrumentation may be required to combat translational and rotational displacements (2).

- In upper thoracic fractures, place supplemental hooks caudal to the injury to avoid a bulky construct under the thinner soft tissues of the upper back.
- In lower thoracic injuries, place the supplemental hooks cranial to the fracture site.
- Never place supplemental hooks at the laminae just above the fractured vertebra, because this places the hook directly opposite any bone fragment retrospulsed into the spinal canal.
- In osteoporotic bone or in face of transverse process fractures, substitute laminolaminar claws for transversopedicular claws.

### Thoracolumbar Junction

- SSPI allows direct reduction of sagittal deformity and translation while instrumenting the shortest possible segment of the lumbar spine.
- Treat thoracolumbar and lumbar fractures with pedicle screws placed immediately above and below the fractured segment.
- In cases of severe axial instability, place offset laminar hooks at the level above the cranial hooks and at the level of the caudal hooks.

If the anterior and middle columns cannot withstand axial loads, a large bending moment is generated at the pedicle screw hub, resulting in a high rate of bending failure. Acute bending failure occurs before a solid arthrodesis has occurred and before anterior column structures have regained enough strength to share compressive loads. Failure during this period results in progressive collapse of the spinal segment, progressive kyphosis, and clinical symptoms. Ebelke et al. (34) found that transpedicular bone grafting eliminated pedicle screw failure in their series (see the section entitled Transpedicular Bone Graft), and similarly, patients with an intact or restored anterior column do not experience screw-bending failure (70).

If care is taken to protect pedicle screws in patients with anterior column instability, SSPI is still an ideal approach for selected patients (Fig. 142.15, Fig. 142.15B). Do not attempt in situ contouring of the rod unless offset laminar hooks are applied to supplement screw fixation. These hooks provide improved clinical results (4, 39) and have been shown to improve construct stiffness and to reduce screw bending moments significantly both in sagittal loading and in situ contouring (22, 83).

**Figure 142.15.** Short-segment pedicle instrumentation. A, B: Lateral and AP views of 38-year-old patient with an L-1 burst fracture and marked sagittal collapse. Synthes Universal System fracture module was applied to correct kyphosis and anterior vertebral collapse. C: Similar fracture pattern treated with Cotrel-Dubousset segmental instrumentation. Because anterior column disruption was not severe, offset hooks were not applied.

Extended pedicle screw constructs are intended to address thoracolumbar fractures with as little alteration of lumbar spinal mechanics as possible (Fig. 142.16).

**Figure 142.16.** Extended pedicle screw constructs. A: Lateral view of 18-year-old patient with L1–L2 fracture-dislocation and incomplete cauda equina syndrome. B: Extended construct using pedicle screws at L-2 and L-3 to stabilize the spinal column, with a down-going supplemental hook to compress the anterior strut graft. C: Extended pattern using supplemental offset hooks to protect pedicle screws. Intermediate hooks are directed cranially to decompress the fracture site indirectly.

- Extend the fixation construct into the lower thoracic region to apply sufficient corrective force to reverse sagittal deformity and restore neutral or lordotic alignment.
- Place pedicle screws just below the level of fracture to limit the extent of lumbar dissection and fusion (47, 70). Pedicle screws may be supplemented with offset hooks.

The weak link in the extended construct, as in the short-segment construct, is the pedicle screw itself. Unless they are supplemented with an offset laminar hook, additional levels of fixation, or an anterior reconstruction, the pedicle screws are exposed to large cantilever bending loads (73, 76). These forces are concentrated at the screw hub, a natural stress riser, and at the contact point between the screw and the lamina (52, 45, 68, 70). Screw breakage that occurs after healing is complete is often asymptomatic (62). Bending failure that occurs before the fracture has consolidated results in progressive material failure and sagittal collapse, and can occur even in braced patients (60, 69, 68). Patients treated with supplemental offset hooks or with an anterior reconstruction do not develop segmental collapse.

An incomplete neurologic deficit is a relative indication for anterior decompression. It should be recognized, however, that canal compromise can be improved through indirect reduction (77, 80), and that bony remodeling improves canal diameter over time irrespective of treatment (71). Still, persistent neural compression can inhibit neurologic recovery (46), and anterior decompression can provide dramatic neurologic improvement in many patients (57, 61). Because functional outcome is more clearly related to the residual neurologic deficit than to any other parameter, we continue to emphasize the need to maximize early neurologic recovery. This entails early recognition, rapid resuscitation, corticosteroid therapy, and surgical decompression when the patient is hemodynamically stable (12, 15, 23).

- Carry out anterior decompression at the thoracolumbar level through a combined thoracoabdominal approach, providing access to the entire thoracolumbar segment.
A T-11 retroperitoneal approach may expose all of L-1 and most of T-12 but access to the fractured vertebra and, particularly, to the canal will be hampered by the intact diaphragm (see Chapter 138). After completing the surgical approach, identify the fractured vertebral body by inspection and confirm the level radiographically. After double-ligating the segmental vessels at the level of the fracture and both vertebral bodies to be instrumented, peel the psoas back from the vertebral body with a Cobb elevator. After elevating the psoas muscle back to the level of the neural foramen, completely debride the disc spaces above and below the fracture of disc material, removing the outer annulus circumferentially to the far side. Debride the posterior annulus back to the rim of the vertebral body and release it with a small curved curet. The discectomies should be relatively bloodless. Release as much of the fractured vertebral as is possible. Once the discs are gone, remove the fractured body piecemeal, taking the near and anterior cortices with double action rongeurs. Remove bone back to the posterior cortex with rongeurs and a high-speed burr, until the bell of the near pedicle is exposed and the posterior vertebral cortex has been identified. Usually, there will be one large fragment of bone locked between the pedicles, attached to the posterolateral annulus. Insinuate a fine, curved curet between the bell of the pedicle and the back rim of this fragment to draw it out of the canal. Once this edge is freed from the overhanging pedicle, deliver the whole fragment anteriorly with the curet and pituitaries. Significant bleeding may be encountered as the posterior cortex is pulled away from the posterior longitudinal ligament (PLL) and the nutrient vessels (Fig. 142.17). Use bipolar cautery and thrombin-soaked gel foam to control this hemorrhage.

**Figure 142.17.** Reduction of retroapsed fragments.

- On completion of the vertebrectomy, the dura should be visible from endplate to endplate and from pedicle to pedicle.
- Then prepare the endplates for reconstruction.

**Lumbar Spine**

Whether for simple stabilization or for instrumentation after decompression, SSPI performs well in fractures of the lumbar spine below L-2. Of the few burst fractures of the lower lumbar spine that require surgical treatment, half will undergo anterior decompression for cauda equina compression, followed by strut graft reconstruction (70). Patients with no neurologic injury typically require posterior SSPI alone. If there is severe vertebral comminution, however, anterior reconstruction may be needed to prevent progressive sagittal collapse (66).

Flexion-distraction injuries through soft tissues or multi-level injuries may benefit from internal fixation by one of two techniques: compression hook constructs or pedicle screw fixation.

- Reduce transverse disruptions by positioning the patient prone on transverse bolsters or the Jackson frame.
- Use a limited exposure of the fracture site, extending to the cranial rim of the first intact lamina above the injury and to the caudal rim of the intact lamina below the injury.
- Debride the disruption of bone fragments, hematoma, and disrupted ligamentum flavum, joint capsule, and muscle. This will prevent the soft tissues from infolding into the canal when the injury is reduced.
- After determining that the facet joints are reduced and the laminar edges aligned, apply a compression construct, with a hook above and one below the intact laminae.
- A Harrington compression rod may be used with two opposing laminar hooks, or a rod/hook combination from any segmental system (44,48,79).
- For more unstable injuries or frank dislocations, pedicle screw instrumentation provides three-column fixation to control axial, translational, and rotational displacements.

Anterior reconstruction of lumbar fractures may follow a decompressive procedure or may be carried out primarily to address axial instability. Anterior plate fixation may be adequate to immobilize the spine in some cases in which the posterior elements have not been injured. In cases in which laminar fractures or soft-tissue disruption have rendered the posterior column incompetent, reinforce anterior reconstruction with concomitant posterior instrumentation. Likewise, anterior reconstruction at the lumbosacral junction will require a posterior instrumentation, because no suitable fixation of the sacrum yet exists.

**Lumbosacral Junction**

Surgical treatment of L-5 burst fractures is rarely necessary (49); the spinal canal is large compared with the volume of its contents, and sagittal imbalance is more easily compensated for than at the thoracolumbar junction.

Traumatic spondylolisthesis is an uncommon injury, occasionally associated with sacral fractures or sacral facet fractures. Progressive deformity or onset of neurologic symptoms requires surgical stabilization, typically with lumbosacral pedicle screw instrumentation. Noninstrumented fusion is an option, but progression of the slip may occur even when fusion is successful.

Severe burst fractures are occasionally associated with pelvic and sacral injuries. These injuries are the result of high-energy trauma, and the patients are severely traumatized. Urgent spinal stabilization is indicated to allow safe treatment of multiple injuries, with early mobilization and aggressive pulmonary therapy. If decompression is needed anteriorly, blood loss may be severe.

- Repair dural tears primarily or with a fascial graft, and reconstruct the vertebrectomy with a tricortical strut or cage.
- Standard anterior instrumentation is not possible because screw fixation to the sacrum is both difficult and tenuous. Immediate posterior instrumentation to prevent graft displacement is indicated, when possible.
- Coordinate reconstruction of pelvic fractures or sacral disruptions with spinal care.

**Sacral Fractures**

Sacral fractures occur most often in patients with pelvic ring fractures, either in association with sacroiliac (SI) joint injuries or as discreet sacral fractures. The treatment of sacral fractures in the context of pelvic trauma is discussed in Chapter 17. There are six basic fracture patterns, as shown in Table 142.2.
Table 142.2. Sacral Fracture Patterns

Injuries of types 4, 5, and 6 have a high incidence of root and cauda equina injury. Residual compression may result in persistent neurologic deficit requiring surgical treatment. Patients with persistent radiculopathy following fracture should undergo a fine-cut CT scan of the sacrum. Neural foraminae with greater than 50% canal compromise may be indicated for surgical decompression.

- Position the patient prone with the abdomen free and a bolster under the pelvis.
- Expose the sacral lamina through a midline incision and perform an L5–S1 laminotomy.
- Then unroof the dural sac by laminectomy down to the S-3 level.
- Identify the involved root (typically S-1) and follow it laterally into the foramen.
- Take the interval between S-1 and S-2 down to the dorsal aspect of the ventral cortex.
- Debride the fracture fragments, fibrous tissue, and hematoma away from the undersurface of the nerve root using down-biting curets, pituitary rongeurs, and small osteotomes.
- Carry out debridement to the anterior aperture of the neuroforamen, or until the compression is relieved and the nerve root is free and mobile.
- Fixation of the fracture is usually not possible. Limit the patient's weight bearing until the fracture has united; patient should avoid sitting up for 2 to 3 months.

**Transverse Sacral Fractures** When a transverse sacral fracture is encountered, laminectomy alone may not be enough to decompress the nerve roots, which are often tented over the kyphotic deformity. This bony prominence must be removed.

- To avoid injuring these roots, carry out a lateral approach to the anterior from between the exposed nerve roots at the level of fracture, usually between S-1 and S-2.
- Use narrow osteotomes and down-biting curets to fragment the retropulsed bone, and decompress the cauda equina.

**PITFALLS AND COMPLICATIONS**

Unless basic biomechanical rules are understood and followed, serious complications can occur following spinal stabilization. Reduction of fractures and fracture dislocations through distraction is a routine maneuver, but overdistraction can widely displace bony elements and stretch the spinal cord, causing serious neurological injury. Also, posterior reconstruction of severe burst fractures without restoring the anterior weight-bearing column exposes instrumentation systems to excessive cantilever-bending forces, resulting in acute pedicle screw-bending failure, or late collapse and fatigue failure. If the normal thoracolumbar lordosis is not restored at the time of surgery, the forces of weight bearing will fall anterior to the lumbar spine and pelvis, imparting an exaggerated flexion moment on the fracture and fixation construct, again predisposing to instrumentation failure. Finally, failure to expose the thecal sack completely—from pedicle to pedicle and endplate to endplate—during an anterior decompression may result in persistent neurologic impairment.

**SUMMARY**

With newer, segmental instrumentation systems, our ability to address the individual "personality" of each spine fracture has improved. Segmental constructs and pedicle screws have improved fixation strength and construct stiffness, allowing us to get patients out of bed, into rehabilitation, and home more rapidly and with better long-term results. Newer implant systems must still be applied with full attention to fracture type and biomechanical principles, or implant failure is sure to occur. Technique and implant design cannot alter the damage done to the spinal cord at injury either, and functional outcomes are most profoundly dependent on neurologic integrity. Further research in spinal cord recovery and regeneration holds the greatest promise for future victims of major spinal trauma.

CERVICAL DISC DISEASE

The pathoanatomy of disc degeneration or spondylosis of the cervical spine can be considered part of the normal aging process. The progressive deterioration that develops is commonly found in asymptomatic individuals but also may lead to neurocompression, radiculopathy, and myelopathy. The presentation of these syndromes depends on the specific structures compromised by the degenerative process. Treatments of axial neck pain, radicular arm pain, and myelopathy are based on a clear understanding of the natural history of the disorders and available therapeutic options. This chapter reviews the pathophysiology of cervical spondylosis and relates it to the development of clinical manifestations, including the evaluation as well as the nonoperative and operative management of such problems.

CERVICAL ANATOMY/PATHOANATOMY

An understanding of normal and pathologic cervical anatomy is essential to appreciate the role of management of the symptomatic patient. The cervical spine comprises seven vertebrae, each possessing five articulations (Fig. 143.1). The cranial two vertebrae, the atlas and axis, are anatomically unique, whereas the third through the seventh (subaxial) vertebrae are more typical. The first two are rarely involved in the degenerative process and are more commonly affected by inflammatory processes such as rheumatoid arthritis (see Chapter 154).

The subaxial vertebral bodies increase in size from cephalad to caudad and are greater in the transverse than in the anteroposterior (AP) dimension (46). They are thicker in height in the anterior aspect of the intervertebral space supporting the lordotic curvature. The intervertebral discs increase range of motion between the vertebral bodies and distribute forces over the length of the spine (46).

The intervertebral disc consists of the central gelatinous nucleus pulposus, the outer annular fibrosis, and the superior and inferior endplate cartilage. The annulus is composed of alternating layers of collagen fibers running in oblique directions. A normal functioning disc will disperse forces by initial expansion of the nucleus pulposus and dispersal of these forces through the annular fibers (46).

The lordosis typically seen in the cervical spine is achieved through the shape and configuration of the intervertebral discs. These discs make up nearly 22% of the overall length of the cervical spine (46). The superior endplate surface is concave, whereas the inferior surface is convex. Uncovertebral joints of Luschka or uncinate processes project from the superoposterior corner of each vertebral body and form a synovium-lined articulation with the corresponding vertebra (32). Short, small pedicles arise from the posterior vertebral body and extend posterolaterally to the lateral masses. The lateral masses are unique to the cervical spine and form superior and inferior articulations via synovium-lined facet joints. The laminae extend posteromedially from the lateral masses and form into the spinous process, which in the cervical spine is ordinarily bifid.

Figure 143.1. Cross-sectional diagram of a normal cervical vertebra. Note the articulations of zygapophyseal facet joints and uncovertebral joints of Luschka.

SOFT DISC HERNIATION

The lordosis typically seen in the cervical spine is achieved through the shape and configuration of the intervertebral discs. These discs make up nearly 22% of the overall length of the cervical spine (46). They are thicker in height in the anterior aspect of the intervertebral space supporting the lordotic curvature. The intervertebral discs increase range of motion between the vertebral bodies and distribute forces over the length of the spine (46).

The intervertebral disc consists of the central gelatinous nucleus pulposus, the outer annular fibrositis, and the superior and inferior endplate cartilage. The annulus is composed of alternating layers of collagen fibers running in oblique directions. A normal functioning disc will disperse forces by initial expansion of the nucleus pulposus and stretching of the annular fibers. This process essentially converts an axial load into horizontal forces absorbed by the annulus (46).

The neuroforamina are clinically important parts of the cervical spine. The neuroforamina are confined zones for the exiting nerve roots, bordered anteriorly by the lateral aspect of the intervertebral disc and the uncovertebral joint, superiorly and inferiorly by the pedicles, and posteriorly by the articular masses, notably the superior articular facet. Pathologic conditions involving these structures can lead to critical stenosis of the foraminal and nerve root compression.

SPONDYLOSIS

The change from normal anatomy to an aging spondylootic cervical spine is subtle and is part of the degenerative cascade. The initial alterations are suspected to occur within the intervertebral disc leading to secondary changes in the surrounding facet joints and soft-tissue structures. Diminished water content along with changes in the ratio of proteoglycan to collagen, and keratin sulfate to chondroitin sulfate are early manifestations of degeneration (60). Because of this, the nucleus pulposus no longer can generate the hydrostatic intradiscal force required to expand the annular fibers. This subjects the annular fibers to compression and shear forces, causing weakening and tearing in the outer layers. Disc protrusion or frank herniation may ensue, with or without neurocompression. Disc dehydration also results in loss of height. This is more prominent in the anterior disc space because the uncovertebral joints impact on the posterior vertebral bodies as collapse occurs, preventing further posterior disc height loss. The combined effect leads to the characteristic loss of cervical lordosis on lateral plain...
Approximation of the vertebral bodies alters the biomechanical forces placed on the uncovertebral joints and articular facet joints. Osteophytic spurring, often referred to as hard disc, may develop, leading to encroachment on the neuroforamina. Similarly, reactive bone forms along the posterior vertebral bodies as the margins come into greater contact when higher forces are applied. A spondylotic transverse bar may subsequently form, in combination with bulging of the posterior disc and stretching of the posterior longitudinal ligament. Further collapse of the anterior column height leads to buckling of the ligamentum flavum into the spinal canal, most notably during neck extension. This combination of events may lead to spondylotic-induced compromise of the AP diameter of the canal.

As the cervical discs degenerate, there are several potential sources of pain. Distortion of the intervertebral disc may lead to stretching or compression of the sinuvertebral nerve and finer nerve endings, with subsequent symptoms. Additionally, distortion or injury of innervated areas such as the apophyseal facet joints, ligamentous structures, and posterior musculature may produce pain.

There are several sites within the spinal canal where neurocompression may occur. Radiculopathy may occur from posterolateral soft disc herniation either contained by the posterior longitudinal ligament (PLL) or as free material extruded into and sequestered within the canal. In addition, foraminal stenosis from the changes previously described may also lead to impingement on the exiting nerve root. OSSIFICATION OF THE POSTERIOR LONGITUDINAL LIGAMENT

Finally, myelopathy may stem from cord compression secondary to ossification of the PLL (OPLL). The ossified mass arising from the PLL has been classified as continuous, extending over several vertebral bodies; segmental, ossification at the level of the posterior vertebral bodies only; mixed continuous and segmental; and localized, with ossification at the level of the disc only.

NATURAL HISTORY OF CERVICAL DISC DISEASE

NECK PAIN

Because of the numerous etiologies that can produce symptoms, establishing a prognosis for a patient with axial neck pain can be difficult. The natural history of neck pain has been evaluated by Gore et al., who performed a retrospective review of patients with neck pain followed clinically and radiographically over a 10-year period. Of these patients, 79% had diminished pain and 43% had nearly complete relief of symptoms. However, nearly one third of the study group reported persistent moderate to severe pain. Outcome could not be correlated with radiographic or clinical findings, making outcome projections difficult for patients with neck pain.

RADICULOPATHY

The natural history of cervical radiculopathy has been well described. Lees and Turner reported on the long-term follow-up of patients with spondylotic and confirmed that 30% of experienced intermittent radicular symptoms and 25% had persistent pain. Progression from radiculopathy to myelopathy is unusual, and most likely these are distinct entities. In general, there is agreement that nonoperative treatment may alleviate symptoms of cervical spondylotic radiculopathy (CSR) in the short term, but over a long period of time symptoms frequently recur. Gore et al. retrospectively reviewed patients with cervical radiculopathy treated conservatively and
noted that 50% had persistent symptoms at 15-year follow-up (36).

**MYELOPATHY**

Cervical spondyloidy myelopathy (CSM) is associated with an insidious onset of symptoms and, in general, neurologic function undergoes episodes of worsening with intervening stable periods (42). However, there are no pathognomonic findings to predict the progression of symptoms (49). Clarke and Robinson evaluated the natural history of CSM prior to treatment and concluded that 75% in their cohort experienced episodic worsening of symptoms; 20% showed slow, steady progression without intervening stabilizing periods; and 5% experienced rapid onset of the disease process and progression (50). Progression to total disability is unusual, although slight incremental neurologic deterioration may occur with time, resulting in upper and lower extremity functional deficits. As the neurologic deficit worsens, improvement of disability becomes more unlikely and complete recovery less likely.

**CLINICAL EVALUATION**

The clinical evaluation of a patient with cervical degenerative disorders requires interpretation of the patient's complaints, meticulous examination, and appropriate selection of diagnostic tests. To perform a complete evaluation of a patient's complaints, first determine if the problem involves neck pain, arm pain, or a combination of both, or whether there is a myelopathic component. A detailed history is the initial step in evaluating a patient with cervical degenerative disc disease. Obtain a complete description of the symptomatology, including the onset, quality, and location of pain; inciting and alleviating factors; temporal nature; degree of impairment; and any associated symptoms.

Axial neck pain may be discogenic or muscular in origin, or it may be related to shoulder, occipitocervical, myofascial, or visceral pathology. To differentiate the potential multiple sources of neck pain, establish whether the symptoms are mechanical (increased with activity and diminished with rest or positioning) or nonmechanical (no relief with positional changes or rest). Nonmechanical neck pain may be related to tumor or infection, and such processes should be carefully sought out. A history of deep-seated aching pain that occurs only at night and is absent or markedly diminished during the day is suggestive of neoplasm or infection. Mechanical neck pain is commonly discogenic in origin and exacerbated with neck extension and rotation toward the side that is more symptomatic. Patients may describe pain referred to the shoulder, upper arm region, or interscapular area. Patients with upper cervical degeneration may also experience occipital or temporal pain, or retro-ocular headaches. Musculogenic pain, as from an acute or chronic muscle strain, is more often exacerbated with neck flexion and rotation, leading to increased symptoms on the opposite side of head rotation.

Radicular symptoms may be caused by a soft lateral disc herniation, chronic disc degeneration with osteophytic spurring, or segmental instability. The majority of patients present with a monoradiculopathy, although several roots can be involved. Symptoms consist of sharp, lancinating, radiating arm pain associated with various degrees of dysesthesia, paresthesia, and numbness along a dermatomal pattern consistent with distribution of the involved nerve root.

The symptoms may be exacerbated or relieved by several provocative tests. Typically, patients will describe an increase in pain with Valsalva activities and with neck extension and extension toward the symptomatic side. A Spurling's sign is indicative of radiculopathy. This is elicited by neck hyperextension and rotation toward the symptomatic side, resulting in reproduction of the pain. This maneuver serves to diminish the available area in an already compromised neuroforamen, leading to further nerve root compression. A less reliable provocative sign is the axial compression test, in which compression on the vertex of the skull may diminish the height of the foramen and also symptoms. The shoulder abduction sign is a test that relieves symptoms of compression by lessening nerve root stretch with placement of the ipsilateral hand on top of the head. Patients may present with this as the only upper extremity position that provides relief or comfort.

The history and examination identify the level of radiculopathy. Typically, the patterns of pain distribution that patients describe are imprecise because of anatomic variations, involvement of multiple levels, or the presence of chronic pain. Upper cervical nerve root compression is less common than lower levels; however, it must be considered in the differential diagnosis of recalcitrant neck pain.

Radiculopathy of the C-3 or C-4 roots will manifest as neck pain radiating to the trapezial, shoulder, and anterolateral area of the chest. The symptoms are described as pain with variable degrees of paresthesia but without a specific motor deficit. A more classic presentation occurs with compression of the lower cervical nerve roots. A C-5 radiculopathy produces radiating pain down the lateral aspect of the shoulder and proximal arm with associated sensory changes and/or increased fatigue or weakness of shoulder abduction. The C-5 root also innervates the deltoid, whereas the biceps has dual innervation from C-5 and C-6.

A C-6 radiculopathy produces neck pain radiating down the biceps and anterior arm to the radial aspect of the forearm and index finger and thumb. The biceps and wrist extensors may demonstrate weakness. The extensor carpi radialis longus and brevis are innervated by C-6, and the extensor carpi ulnaris is primarily C-7. Therefore, wrist extensor weakness may reflect compression of either C-6 or C-7. The brachioradialis reflex is most directly affected with C-6 compression with subtle changes noted in the biceps reflex due to its dual innervation.

Compressive pathology of the C-7 nerve root presents with pain along the posterior shoulder and arm, radiating to the posterolateral aspect of the forearm to the long finger. Inconsistent symptoms involving the index and ring digits as well as the first web space may also be detected. The triceps muscle is affected, resulting in a diminished reflex and elbow extensor weakness. Triceps weakness is an infrequent complaint, unless the patient is physically active.

A C-8 radiculopathy is characterized by pain referred to the ulnar aspect of the forearm, small finger, and ulnar half of the ring finger. The findings are primarily below the elbow, with most dysfunction noted as numbness along the ulnar digits and weakness in finger adduction, abduction, and flexion. In chronic C-8 root compression, intrinsic muscle atrophy may be seen.

The symptoms of cervical radiculopathy are variable and complaints may be vague, so myelopathy is not easily picked up on the initial examination (17,23). Symptoms and findings can include gait difficulties, spasticity, decreased manual dexterity, paresthesias in the extremities, urinary urgency or frequency, and specific extremity or generalized weakness (52). In contrast to cervical radiculopathy, pain is not a common presenting finding. Depending on the site of anatomic spinal cord compression, the symptoms may be quite variable.

The gait disturbance may be an early presenting complaint. Patients describe insidious and slowly progressive stumbling or generalized gait disturbances. Patients may initially become aware of these changes from family members who note a shuffling gait or frequent falls. The characteristic stooped, wide-based gait of the elderly is the common end result. Involvement of the upper extremities may occur concomitantly or follow the gait changes, with complaints of clumsy or numb hands. Weakness of the hand manifests as decreased grip strength. Manual dexterity will often suffer and progress until the patient lacks the ability to complete routine activities such as buttoning a shirt, counting change, or writing. Several researchers have noted characteristic hand dysfunction in cervical myelopathy. For example, Ono et al. reported on the myelopathic hand syndrome, describing the finger escape sign and grip and release test (49). Clarke and Robinson evaluated the natural history of the myelopathic hand syndrome, describing the finger escape sign and grip and release test (50). The finger escape sign is positive when the patient is asked to hold all the digits of her hand in an adducted and extended position and the two ulnar digits fall into abduction and flexion with time. In the grip and release test, the patient is asked to rapidly form a fist and then release all digits into extension repeatedly. A patient without myelopathy should be able to perform this test 20 times in a 10-second period.

Physical examination of a myelopathic patient consists of thorough neurologic and other special testing. The presence of lower extremity clonus and Babinski extensor plantar responses should be noted. The Hoffmann's reflex (finger and thumb interphalangeal flexion with sudden long finger distal interphalangeal joint extension) when present, and especially when asymmetrical, is strongly suggestive of cervical myelopathy (Figs. 143.5). Other tests that may be noted include an inverted radial reflex, a scapulohumeral reflex, and Lhermitte's sign (43).

**Figure 143.5.** Hoffmann's reflex is indicative of cervical cord impingement. The reflex is positive if the fingers and thumb react in flexion when the long finger distal...
Surgical exposure of the anterior aspect of the cervical spine is a relatively safe procedure that takes advantage of normal anatomic fascial planes during the approach.

Anterior Cervical Discectomy and Fusion (ACDF/ACD), anterior corpectomy with fusion (ACF), posterior laminotomy with foraminotomy, or laminectomy or laminoplasty with or without fusion may be performed to treat cervical radiculopathy and myelopathy due to herniated disc, spondylolysis, or spondylolisthesis. These procedures are indicated when nonoperative treatment has failed to provide relief of symptoms.

The indications for operative intervention in cervical radiculopathy include (a) failure of a 3-month trial of nonoperative treatment to relieve persistent or recurrent radicular arm pain with or without neurologic deficit, and (b) a progressive neurologic deficit. Neuroradiographic findings must be consistent with the clinical signs and symptoms, and the duration and magnitude of symptoms must be sufficient to justify surgery.

The operative approaches utilized for radiculopathy include anterior decompression with discectomy [anterior cervical discectomy without fusion (ACDF/ACD)], anterior corpectomy with fusion (ACF), posterior laminotomy with foraminotomy, or laminectomy or laminoplasty with or without fusion (Table 143.1).

Place the patient in the supine position with a small roll placed under the shoulder blades to drop the shoulders from the field and to present the anterior neck favorably. Strap the shoulders at the side with minimal traction to allow visualization of the lower cervical spine on lateral radiographs.

Apply skull traction via a chin halter device or with Gardner-Wells tongs. Keep head rotation to a minimum because deep dissection will depend on identifying the vertebral midline to prevent inadvertent injury to adjacent structures. The reverse Trendelenburg position facilitates venous drainage and results in less bleeding during surgery.

The superficial anatomic landmarks for incision include the hyoid bone overlying C-3, thyroid cartilage overlying the C4–5 interspace, and cricoïd cartilage overlying the C-6 level. Use transverse incision for exposure in most cases when one or two discs are to be exposed. When three or more levels are approached, use a longitudinal incision along the anterior border of the sternocleidomastoid muscle. The transverse incision is preferred for its cosmetic appeal and access to the anterior spine, whereas the longitudinal incision serves to improve visualization of the region over multiple levels and avoids excessive retraction that may otherwise be necessary.

Bluntly dissect the pretracheal fascia and palpate the carotid pulse. Dissection through the pretracheal fascia places several structures at risk. The superior and inferior thyroid arteries extend through the pretracheal fascia from the carotid artery to the midline. The superior and inferior thyroid arteries travel at the C3–C4 and C6–C7 levels, respectively. The intervening area provides a relatively avascular plane for dissection. The recurrent laryngeal nerves are also at risk during the anterior approach. The right recurrent laryngeal nerve ascends in the neck after passing around the aortic arch along the tracheoesophageal groove in a more midline and protected position. A left-sided procedure may be safer, especially when lower cervical segments are approached. However, the thoracic duct is often visible on the left at the C7–T1 level and must be protected.

Retract the sternocleidomastoid muscle and the carotid sheath along with its contents (common carotid artery, internal jugular vein, and vagus nerve) laterally, and retract the midline structures, including the trachea, esophagus, and thyroid gland medially.

Complete blunt dissection through the deeper levels to the prevertebral fascia and vertebral bodies.

Once the midline is identified, incise the prevertebral fascia and elevate the medial edges of the longus colli muscles.

Place blunt self-retaining retractors under the leading edges of the muscle. Take care to avoid dissecting along the longus colli muscle because injury to the cervical sympathetic plexus is likely.

Identify the vertebral bodies by their concave appearance and the discs by their more convex contour.

Localize the disc space with a radiopaque marker and lateral radiograph.

Incise the disc with an annulotomy blade and perform the decompression.

Remove the disc contents and endplate cartilage to the PLL (Fig. 143.6A, Fig. 143.6B and Fig. 143.6C). The proper technique of discectomy involves removal of disc material in a posterior to anterior direction and lateral to medial away from the vertebral arteries. Use thorough evaluative preoperative imaging to determine the presence of a sequestered disc behind the PLL. Palpate the PLL for the presence of a rent that may also indicate a sequestered fragment. In the event that a rent is noted, or if an expected disc fragment is not identified, remove the PLL with Kerrison rongeurs or curets. Beware of routine removal of the PLL, because reports of postoperative epidural hematoma have been associated with this technique (70).

Incise the disc with an annulotomy blade and perform the decompression.

Remove the disc contents and endplate cartilage to the PLL (Fig. 143.6A, Fig. 143.6B and Fig. 143.6C). The proper technique of discectomy involves removal of disc material in a posterior to anterior direction and lateral to medial away from the vertebral arteries. Use thorough evaluative preoperative imaging to determine the presence of a sequestered disc behind the PLL. Palpate the PLL for the presence of a rent that may also indicate a sequestered fragment. In the event that a rent is noted, or if an expected disc fragment is not identified, remove the PLL with Kerrison rongeurs or curets. Beware of routine removal of the PLL, because reports of postoperative epidural hematoma have been associated with this technique (70).

Several techniques of anterior interbody fusion in the cervical spine have been described; they differ by graft configuration (Fig. 143.7).

**Types of anterior cervical grafts used in interbody arthrodesis.**

**Robinson Technique** The Robinson interbody fusion technique involves the placement of a tricortical iliac crest wedge graft into the disc space for bony healing.

The graft height should be 2 mm greater than the preexisting disc height, or at least 5 mm, to obtain adequate compressive strength and to enlarge the neural foramina (1). Overdistraction of the disc space by greater than 4 mm of the preexisting height may result in graft collapse and pseudarthrosis (14). Achieve distraction of the fusion space with skull traction, laminar spreader, vertebral screws, or combinations of these.

Burr the endplates to create a flat surface on both sides of the intervertebral space. Additionally, small holes may be created in the endplates to promote vascularization of the graft.

After measuring the depth and width of the disc space, harvest the tricortical graft from the anterior iliac region. Obtain the graft with an oscillating bone saw, because graft weakening has been associated with the use of osteotomes (37).

Contour the graft to fit into the disc space and insert it with the leading cortical edge anteriorly and inset 2 mm beyond the vertebral bodies. The graft may also be inserted in the reverse position, with the leading cortex directed posteriorly, to maximize posterior disc space and foraminal distraction. This has been shown to be an acceptable alternative to the more traditional graft position. The graft should be stable with compression after removal of all traction devices.

**Coward Technique** The Coward technique utilizes a bicortical dowel-shaped graft (19). The technique requires the use of specialized instruments including drills, guards, and a dowel cutter.

![Figure 143.7](image-url)
Simmons Technique  The Simmons technique for interbody fusion utilizes a keystone-shaped graft (59).

- After completion of the discectomy, remove bone from the inferior aspect of the superior vertebral body and the superior aspect of the inferior vertebral body with specialized osteotomes.
- The end of the vertebra is beveled to an angle of between 14° and 18°, as recommended by Simmons and Bhalla (59). Maximally distract the neck and measure the graft site.
- Harvest a rectangular iliac crest graft and contour to match the beveled surfaces of the vertebral bodies.
- After the graft is impacted in the host bed, release the traction, thus locking the graft in place.

Bailey and Badgley Technique  The Bailey and Badgley technique involves developing an anterior trough in the vertebral bodies to accomplish fusion (3).

- Make a trough ½ inch wide and 5/16 inch in depth along the full length of the vertebral bodies to be fused.
- Remove the intervening disc and endplate cartilage to a depth of 5/16 inch and impact a unicortical iliac crest graft into place. Insert the graft with the neck in extension and, after placement, flex the neck to achieve stability.

The Cloward and the Bailey and Badgley techniques have the disadvantage of having no direct nerve root decompression, and thus are seldom used today.

Because iliac crest bone harvesting has an associated morbidity, the use of allograft bone has become a popular method of interbody fusion. In one study, although nonunion rates and graft collapse were more common in ACDF with freeze-dried tricortical iliac crest allograft, the clinical results were similar to ACDF with autogenous bone graft (77). Fibular allograft has also been shown to provide results similar to autograft, with acceptable single-level fusion rates and the absence of donor site pain (74). Other studies have found a higher radiographic nonunion rate with allograft and greater clinical improvement when autograft is used (44). Therefore, the results of using autograft bone are difficult to evaluate. One-level fusion with allograft may be acceptable, but graft collapse and radiolucencies may persist.

The presence of fusion following discectomy has not been uniformly correlated with a favorable clinical outcome, nor has nonunion consistently resulted in a clinical failure (40). The fact that a pseudarthrosis may be associated with a good clinical result led to the concept of ACD. A major advantage of ACD is the lack of donor site complications. However, the disadvantage is postoperative neck pain, which may become severe and is more common than when ACDF is performed (71). Postdiscectomy collapse and angular kyphosis may also occur, leading to recurrent nerve root compression if posterior osteophytes are not widely resected at the index procedure. Bilateral foraminotomies must be performed to prevent contralateral radiculopathy due to resultant disc space collapse. If ACD is to be performed, it most likely should be limited to soft disc herniations and avoided in patients with evidence of spondylosis who require disc space distraction.

Anterior Cervical Corpectomy

A partial or complete anterior corpectomy and strut graft fusion (ACF) may be necessary in situations in which disc herniation is associated with a sequestered fragment that has migrated behind the vertebral body. Subtotal anterior corpectomy and fusion may also be performed when two-level disc disease is present. The theoretical advantage of ACF over two-level ACDF resides in the number of sites that must fuse.

- Accomplish anterior cervical corpectomy by discectomy above and below the vertebra in question. Then excise the vertebral body with rongeurs or a high-speed burr to the posterior cortex.
- Next, remove the posterior shell with angled curets directed away from the dura.
- Traction or distraction may then be applied to restore sagittal plane alignment at the decompressed level.
- Harvest an iliac crest strut graft and insert it into the prepared endplates, and countersink it slightly into the vertebral bodies. Assess stability of the graft with traction released and, if necessary, consider application of a rigid external orthosis, halo, or internal fixation such as an anterior cervical plate.

Posterior Decompression

Posterior decompression for cervical radiculopathy can be performed with laminotomy and foraminotomy, laminectomy, or laminoplasty (Fig. 143.8, Fig. 143.9). Careful patient positioning is required to minimize the risk of neurologic injury and to maximize exposure of the required level.

Laminoforaminotomy

- Stabilize the head in the prone position with Mayfield skull tongs, leaving the face free without sources of pressure. The reverse Trendelenburg position promotes epidural venous drainage. The posterior approach to the cervical spine utilizes an internervous plane in the midline which separates the muscles from the segmental innervation supplied by the right and left posterior rami of the cervical nerves.
- Incise the ligamentum nuchae in the midline and carry the subperiosteal dissection down the spinous processes and corresponding laminae. In the cervical spine, the laminae do not overlap each other as much as in the thoracic spine; therefore, the interlaminar space may be inadvertently penetrated if caution is not taken during the exposure.
- Carry dissection out to the lateral edge of the lateral masses and preserve the facet joint capsule if no fusion is required or anticipated.
- Remove portions of the inferior and superior laminae at the level of the specific nerve root compression and perform partial facetectomy with a high-speed burr.
- To prevent iatrogenic instability, remove no more than 50% of the facet (78). The lamina and thinned bone should be gently lifted off the nerve and spinal cord
with small angled curetes.
- Assess foraminoectomy by placing a blunt probe or Woodson dental instrument into the neuroforamen to judge its patency.
- If disc removal is deemed necessary, expose the nerve root and cauterize the surrounding venous plexus. Gently retract the nerve root cephalad and remove the disc tissue.

Laminectomy Laminectomy is an option for treating multilevel spondylotic radiculopathy with anterior bony ankylosis when cervical lordosis has been preserved.
- Perform laminectomy by thinning the cortices at the junction of the laminae and lateral masses bilaterally with a power burr.
- Use a small Kerrison rongeur to complete the cut and a small angled curette to elevate the laminae.
- Cauterize the adherent underlying venous plexus to minimize epidural hematoma formation.
- Loss of the posterior structural support of the bony elements may increase the risk of subsequent vertebral subluxation and kyphotic deformity, especially in younger patients, in whom fusion should be considered at the time of decompression.

Laminoplasty Laminoplasty may be used in the treatment of multilevel spondylotic radiculopathy with predominantly unilateral symptoms. There are several methods of laminoplasty, which vary by location of the hinge and means of maintaining the open position (36).
- As in laminectomy, perform laminoplasty by thinning the cortex at the lamina and lateral mass junction with a high-speed burr bilaterally to the inner cortex.
- Thin the hinged side without completing the cut while completing the osteotomy on the opening side.
- Gently open the lamina either with towel clips placed through the respective spinous processes or with a vertebral spreader placed into the defect. Fracture the thinned inner cortex of the hinged side and hold the posterior elements open.

CERVICAL MYELOPATHY

The surgical indications for the treatment of cervical myelopathy are not as well defined as they are for the treatment of cervical radiculopathy. A patient with mild, nonprogressive myelopathy that is long-standing and does not cause significant disability can be observed closely. Operative intervention is recommended for (a) progressive myelopathy, (b) moderate or severe myelopathy that is stable and of short duration (less than 1 year), and (c) mild myelopathy that affects routine activities of daily living. The age of the patient or severity of the disease should not serve as a contraindication for surgery; it must be conveyed to the patient that the goal of surgery is to prevent neurologic worsening. Based on the clinical and radiographic evaluation, decide whether to approach the area of compression with an anterior technique, a posterior technique, or a combination (Table 143.2). The factors that are critical in this decision process are the site of compression, presence or absence of spinal stability, sagittal alignment of the cervical spine, and extent of the disease process (41).

| Table 143.2. Indications for the Operative Treatment of Cervical Myelopathy |
|-----------------------------|--------------------------|

The presence of primarily anterior compression of the spinal cord limited to the intervertebral disc space without intervening stenosis of the canal at the vertebral body level indicates an anterior decompression. Anterior decompression can be performed with ACFD using the techniques described. Remove the spondylotic ridge, as well as any other areas of spur formation deemed clinically significant that may require hemi-corpectomy. If multilevel disease is present, consider anterior corpectomy and strut graft fusion. When compressive pathology is present at the disc level as well as posterior to the vertebral body, as with OPLL, then an ACDF will increase the AP diameter at the disc level only and not the remainder of the spinal canal. Anterior corpectomy allows more complete decompression.

If myelopathy is present along with a kyphotic alignment, an anterior decompression is also indicated. This is best performed with ACF to realign and decompress the spine. When accompanied by significant subluxations, kyphosis may need to be approached from a combined anterior and posterior direction. In the presence of spondylotic spurring and a congenitally tight spinal canal over several segments, consider the posterior approach. A compression ratio of less than 0.5 (sagittal diameter divided by the transverse diameter of the spinal cord) may also indicate a posterior decompression (43). This can be performed with laminectomy or laminoplasty, as previously described.

Anterior corpectomy is performed through a transverse or longitudinal incision, based on the number of levels involved. Decompression of the spinal cord is accomplished by removal of the middle third of the vertebral body. Recommendations for safe decompression to within 5 mm of the transverse foramen allow removal of disc or bone 7.5 mm lateral to the midline at C-3 and 9.5 mm at C-6, which can be estimated intraoperatively (63). Because patient anatomy varies, evaluate this on an individual basis based on the preoperative imaging studies. In anterior decompression for OPLL, a “floating procedure” may be performed (72). The anterior ossified mass is not actually removed but rather is released from its surrounding attachments. The localized OPLL segment mass migrates anteriorly and allows decompression of the spinal cord. Because it is possible to encounter absence of the dura or coalescence of dura and PLL in the anterior approach to OPLL, this form of decompression is often recommended (61).

Strut graft fusion is performed with iliac crest when up to two vertebral bodies are removed, but because of its curvature this graft is less useful when longer struts are needed. In corpectomies of three or more levels, a fibular graft is indicated. The iliac crest graft has more exposed cancellous sites for incorporation, but the fibula is mechanically stronger.

SPINAL INSTRUMENTATION

The role of instrumentation in the surgical management of cervical radiculopathy and myelopathy is less clear than in traumatic conditions (Fig. 143.10). In degenerative disc disease, various studies suggest that nonunion rates and graft dislodgement increase with the number of levels operated on (8,76). The goals of applying instrumentation are to provide immediate stability, increase fusion rate, prevent loss of fixation of the bone graft, improve postoperative rehabilitation, and possibly avoid the requirements for an external orthosis (34).
Depuy-Acromed, Cleveland, OH). This patient, who had a history of cigarette smoking, underwent anterior fusion with plating for cervical radiculopathy with neck pain. The plate was used to improve fusion. B: Lateral radiograph shows strut grafting and anterior plating from C-4 to C-7 (the Orion Plate, Sofamor-Danek, Inc., Memphis, TN). This patient underwent anterior corpectomy and fusion for cervical spondylotic myelopathy. C: Lateral radiograph shows laminectomy and lateral mass plating from C-3 to C-7 (Axis Plate, Sofamor-Danek, Inc., Memphis, TN). This patient underwent the procedure for myelopathy due to multilevel cervical spondylosis.

Animal studies have not shown evidence of improved fusion rates of three-level ACDF with plating (76). Avascularity beneath the plate has also been detected, although its significance is unclear. It is doubtful that anterior plating for single-level ACDF increases fusion rate (21). The potential benefits of instrumentation may not outweigh the risks in these situations. Whether multiple-level ACDF fusion is improved by instrumentation remains to be determined, and presently no guidelines are available for their use. Two-level ACDF has a higher pseudarthrosis rate than single levels, and instrumentation is often used in certain situations such as patients who are actively smoking. Although rare, three-level ACDF may be accompanied by anterior plating; however, no scientific data support its use. The main use of anterior plating in ACF is to prevent graft dislodgement. When long graft constructs are used, a plate may be inserted at the inferior vertebral as a buttress where graft displacement most commonly occurs (75).

The role of posterior instrumentation in degenerative conditions is also controversial. Posterior decompressive laminectomy may require concomitant fusion in patients with preexisting instability based on imaging studies. Whether the addition of instrumentation such as lateral mass plating or facet joint wiring increases fusion rate while improving the postoperative course is unknown.

POSTOPERATIVE MANAGEMENT—RESULTS

Patients who undergo anterior cervical spine surgery are allowed to gradually increase their postoperative activities and are encouraged out of bed with directed therapy as needed. Liquids are started with a gradual advance to solids as tolerated. Brace management is controversial and dealt with on an individualized basis. Patients recovering from one- or two-level ACDF may be treated in a rigid or soft orthosis based on their surgeon’s preference. We recommend rigid external orthoses in ACDF, especially when multilevel decompression and fusion are performed in the absence of anterior plating. Such devices include Philadelphia collars or, in severely osteoporotic individuals, halo-vest immobilization. External wear may continue for 6–12 weeks based on radiographic progression of the fusion and the patient’s comfort level. A gradual weaning process may follow from a rigid to a soft collar to no immobilization. A soft collar is all that is needed for posterior laminotomy, laminectomy, or laminaoplasty when performed in the absence of fusion.

Postoperative results of surgical treatment of cervical radiculopathy and myelopathy vary, depending on the type of approach utilized and the severity of the disease. Literature review is depicted in Table 143.3 and Table 143.4. Limitations in drawing firm conclusions from previous reports stem from the lack of uniform patient population, inclusion of different disease processes in the same analysis (soft versus hard disc), and inconsistency of establishing successful results. Overall, the surgical treatment of radiculopathy yields satisfactory results in greater than 90% of patients. Although controversial, it appears that patients who attain a solid fusion do have better outcomes than those with a pseudarthrosis. The results of treatment of myelopathy also are variable, as depicted by the numerous techniques utilized to decompress the spinal cord. Overall, patients with greater neurologic deficits tend to experience less improvement in symptoms following surgery than those with more acute and less severe neurologic findings.

PITFALLS AND COMPLICATIONS

The anterior surgical approach to cervical disc disease involves dissection and retraction of numerous vital vascular, respiratory, neural, and intestinal structures. An overall 0.2% incidence of neck site complications based on an extensive review of published series has been reported in one series (67). It is with an understanding of the potential complications that may occur that improvements in techniques and results may follow.

The incidence of vocal cord paralysis from recurrent laryngeal nerve injury ranges from 1% to 11% of all neurologic injuries (33). The possible causes are traumatic division, stretch injury, compression from postoperative swelling, and injury from thermal necrosis. Injury is much more likely during a right-sided approach because the right subclavian is occasionally anomalous. In these cases, the right recurrent laryngeal nerve, having no vessel to follow, may cross the surgical field directly and may be easily injured during exposure to the mid-cervical spine. The injury is manifested as a hoarse, weak voice with a risk of aspiration due to the inability to completely close the larynx. When symptoms persist for longer than 6 weeks, referral to an otolaryngologist is recommended for evaluation and possible vocal cord injection.

Sympathetic chain injury is also uncommon and manifests as ipsilateral miosis, ptosis, and anhidrosis. Treatment options are limited.

Midline soft tissue injury to the trachea, esophagus, and pharynx are likewise unusual. Dysphagia following anterior cervical surgery is common and is estimated to occur transiently in 8% of patients. When persistent symptoms develop, evaluation should include a lateral radiograph to check bone graft position. Esophageal lacerations occur in 0.25% to 0.7% of patients (38). When identified, immediate primary repair should be performed, the wound appropriately drained, and the patient started on broad-spectrum antibiotics.

Vascular injuries during the surgical approach or decompression are rare but can have devastating sequelae. The structures that may potentially be injured include the carotid sheath contents, superior and inferior thyroid arteries, and vertebral artery. Avoid overzealous retraction and use blunt-edged retractors to reduce the risk of injury to these vessels. Knowledge of the anatomy of the vertebral artery and its relationship to the lateral disc space and vertebral body, as well as maintaining midline
orientation during decompression, all serve to minimize the risk of injury estimated to occur in 0.3% to 0.5% of patients (62). The thoracic duct is at some risk during left-sided approaches to the cervicocaudal junction. If a chylous effusion is encountered, injury to the duct must be suspected.

Spinal cord injury is perhaps the most devastating complication that can occur in anterior cervical surgery. An incidence of 0.1% to 0.64% has been reported in the literature (28). The literature indicates that the drill and dowel technique and the presence of myelopathy are the major risk factors for neurologic injury. In addition, neck manipulation during intubation, cervical malalignment following decompression and grafting, and postoperative epidural hematoma must all be considered in the evaluation of the patient with postoperative neurologic deterioration. Management should include maintenance of normotensive blood pressure, administration of steroids, and imaging studies to assess for possible graft dislodgement (60). If compressive pathology is identified, rapid reexploration and decompression are indicated.

Pseudarthrosis rates following anterior grafting procedures range from 0% to 26% (19,20,24,55,57,66,69). Estimates for fusion for single-level, two-level, and three-level ACDF are 88% to 90%, 73% to 80%, and 70%, respectively (9,76). Even though bony union may not occur, a stable fibrous union can develop and account for the lack of symptoms in some patients with pseudarthrosis. However, several reports have found better clinical results when solid fusion is attained (9,55,68).

Bone graft site complications are not infrequent, with a 20% incidence reported (67). Injury to superficial nerves may result in numbness or pain with neurroma formation. Superior gluteal artery injury has also been reported in iliac crest bone harvest as well as iliac crest fracture.

Complications associated with the posterior approach to cervical degenerative disc disease may also occur. The risk of hematoma can be diminished with strict attention to dissection within the ligamentum nuchae and subperiosteally along the laminae. Reattachment of the paraspinal muscles, especially to the C-2 spinal process, may prevent loss of cervical lordosis following posterior decompression (61).

Neurologic injuries are rare during the posterior approach, although they are more common than with anterior surgery (28). Avoidance of placement of instruments into the spinal canal and thinning of the cortex with a high-speed burr followed by the use of cures during decompression may diminish the risk of neurologic injury.

AUTHORS’ TECHNIQUES

The clinical syndromes of neck pain, radiculopathy, and myelopathy require extensive preoperative evaluation, and when indicated, surgery must be directed at the specific pathology leading to symptoms (Table 143.1, Table 143.2). We manage cervical radiculopathy based on the number of levels involved and the degree of neck pain present. Significant neck pain and up to two levels of radicular symptoms are managed with anterior cervical disectomy and fusion. Radiculopathy without significant neck pain is managed with posterior laminoforaminotomy. In the uncommon situation in which a migrated disc fragment is located behind the vertebral body, a subtotal corpectomy followed by strut graft fusion is the preferred treatment. Radiculopathy involving three levels or more is managed by laminoforaminotomy or laminoplasty for unilateral and laminectomy for bilateral symptoms. Laminectomy is frequently accompanied by lateral mass plating if there is associated instability. Another option is multilevel anterior disectomy and fusion with plating. For these multilevel cases, the anterior approach is preferred if there is loss of cervical lordosis, and the posterior approach is preferred if there is maintenance of lordosis.

Our approach to the treatment of myelopathy considers the site of spinal cord compression and the sagittal alignment of the cervical spine. Single- or two-level disease is treated with anterior decompression and fusion either with ACDF, if impingement is at the disc level, or with subtotal corpectomy if compression is behind the vertebral body. Multiple-level compression at greater than two levels is managed with anterior decompression and fusion with anterior decompression, depending on the pathology identified. Myelopathy with cervical kyphosis is approached with anterior decompression and strut graft fusion. Laminoplasty or laminectomy plus lateral mass plating and fusion is recommended for three- or more level disease with maintenance of cervical lordosis. If there is significant neck pain in addition to myelopathy, fusion is preferred over laminoplasty. Combined anterior and posterior decompression and fusion may be performed when severe circumferential cord compression is present.

CONCLUSIONS

When evaluating patients with cervical degenerative conditions, the physician must be attentive to symptoms and signs of radiculopathy and myelopathy. Appropriate selection of imaging and other diagnostic tests is important for making the correct diagnosis and for cost-effectiveness. The treatment of patients with cervical disc disease is largely nonoperative. Only those patients who failed conservative treatment should undergo surgery for symptomatic relief of radicular arm pain or improvement of neurologic deficits. Patients with cervical spondylotic myelopathy should be treated more aggressively to prevent permanent loss of neurologic function. The choice of anterior versus posterior approach depends on the patient’s symptoms, the location of neural compression, the sagittal alignment, the number of levels involved, and the surgeon’s preference.

CHAPTER 144

LUMBAR DISC HERNIATION

Dan M. Spengler

This chapter focuses on the evaluation and management of the patient with low back pain or sciatica, or both, that results from a herniation of a lumbar disc. The gold standard technique using open lumbar discectomy with loupe magnification is presented. In addition, the technical options for removing a lateral extraforaminal disc herniation are also discussed, as are pitfalls and complications. The most important concern regarding the management of lumbar disc herniation is selection of the appropriate patient for surgery than it is the technique for removal, assuming that a competent surgeon performs an adequate decompression.

ETIOLOGY OF LUMBAR HERNIATION

This is a multifactorial problem and we still do not understand the precise cause for lumbar disc herniation in any given patient. Why is it that one person develops a lumbar disc herniation and another person does not? Patients with lumbar disc herniations are commonly seen in clinical practice. Fortunately, the majority of these patients respond to nonoperative management and do not require surgical removal of the disc. The reason for this improvement remains elusive, although recent work by Haro et al. (6) suggests that a local inflammatory process in the epidural space may stimulate host macrophages to resorb the displaced disc tissue.

From a biomedical perspective, Farfan (4) has shown that lumbar disc herniation may be reflective of high stresses at the posterolateral region of the disc secondary to torsion. These high loads cause fatigue failure of the annulus fibrosis that enables the inner nucleus pulposus to penetrate the laminations of the annulus gradually until a herniation occurs (4). Because the region of the disc with the highest torsional stresses is adjacent to the nerve root, these posterolateral herniations nearly always affect the exiting root or the central thecal sac. Less commonly, the disc may protrude into the extraforaminal area and produce compromise of the more proximal exiting root (e.g., L-4 for a lateral L4–L5 herniation).

Many authors have examined various factors that may represent predictors or risk factors for a lumbar disc herniation (2,3,9,15,16 and 17). The factors that seem to emerge as possibly being predictive include tall men, heavy women, individuals with a small spinal canal, and those who work in an environment with considerable vibration, such as that of airplane pilots and heavy equipment operators (2).

NATURAL HISTORY

In a controlled, prospective long-term study, Weber (20) randomized 126 patients between surgical and nonsurgical treatments. At 1 year, those in the surgical group had fewer pain complaints. At 4 years, there was no statistically significant difference between the two groups. Weber was not a surgeon, and he had no bias toward the efficacy of surgery. One can conclude that surgical intervention should be limited to patients with a significant neurologic deficit or to those patients who are unable to engage in the lifestyle they desire because of sciatica. Weber (20) also demonstrated that less than 2% of the patients in both groups remained symptomatic at the end of 10 years.

ASSESSMENT AND DIAGNOSIS

In patients with the acute onset of sciatica, perform a general history and physical examination. If no findings are identified that suggest another disease process, and the history and physical exam are consistent with a lumbar disc herniation without major neurologic compromise, initiate nonoperative treatment without imaging studies. Many patients improve rapidly and do not require further diagnostic testing. Those patients who do not improve within 30 days and who wish a prompt resolution of their problem warrant a thorough assessment. Plain radiographs with an anteroposterior (AP) and lateral flexion-extension views are useful to document hypermobility patterns or any spinal deformity. Obtain an magnetic resonance imaging (MRI) scan to characterize any disc pathology, localize any herniation, and exclude other conditions such as a spinal cord tumor or tethered cord. If the MRI reveals herniations at numerous disc levels, or if the patient has a contraindication to having an MRI (e.g., claustrophobia, intracranial vascular clips), obtain a computed tomography (CT) scan or myelogram.

I also request my patients to complete a pain drawing to evaluate the psychological characteristics of the patient. The pain drawing has been shown to correlate well with more formalized psychological testing (13). Psychological factors have been shown to be important predictors of outcome and, therefore, are of value to the surgeon (19).

I continue to formulate my surgical recommendation for patients by using the objective patient evaluation system (OPES) (19) (Table 144.1). If a patient has less than 50 points on this system, I recommend nonoperative management. More recently, we have found that even patients who have lumbar disc herniation with more than 50 points on the OPES will not necessarily achieve a “good outcome,” as we previously reported (11). If the patient has engaged an attorney to assist with a compensation claim or if the patient has an attorney who is involved in a civil claim, such as for a car accident, the likelihood for a good clinical outcome drops approximately 30% (11).

Table 144.1. Objective Patient Evaluation System

Patients who present with profound neurologic deficits, such as complete foot drop or cauda equina syndrome, require prompt imaging studies and early surgical decompression. These patients will not be discussed in this chapter because the focus here is on elective lumbar discectomy.
NONOPERATIVE MANAGEMENT

In approaching patients with lumbar disc herniations, it is imperative to formulate a good nonoperative treatment plan. The initial goal is to control symptoms. Once symptoms are controlled, start an activation program. Such a program should include both an aerobic conditioning component and trunk muscle strengthening. In the majority of patients, symptoms can be controlled with nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen (Tylenol), or salicylates. Narcotic medications are occasionally necessary in the first few days of the acute phase, but do not use narcotics for long-term pain control. Steroid dose packs have not been shown to be effective in a controlled study (7). Bed rest may be useful for 1 to 2 days but no longer. As the patient improves, implement a self-guided or supervised physical therapy program to enhance aerobic activity and to improve trunk strength. I prefer resistive exercise equipment such as Cybex, Nautilus, and therabands to strengthen both trunk flexors and extensors. Limit range of motion to 30° of flexion and 30° of extension if resistive equipment is used. If the patient demonstrates good progress, he or she can resume full activities at approximately 3 months after onset, assuming that there is full compliance with an activation program.

Although I do use epidural injections in selected patients with back or radicular pain, I avoid these injections in a patient with lumbar disc herniation, especially if a neural deficit is present. No prospective study has demonstrated success with the use of epidural injections in patients with a lumbar disc herniation.

**AUTHOR'S PERSPECTIVE**

My indications for lumbar discectomy are based on the OPES (Table 144.1) (15). I recommend an elective discectomy only if the patient has failed to respond to a minimum of 30 days of nonoperative management. The patient must demonstrate that his or her quality of life is sufficiently impaired to warrant an elective spinal procedure. Finally, the patient must have a minimum of 50 points on the OPES (15). The technique that I select for surgery has nothing to do with the indications. Once I am comfortable that the patient understands the diagnosis and alternate treatment options, I select the optimal procedure for the patient based on the preoperative imaging studies as well as my knowledge and experience.

I believe that the gold standard surgical procedure for patient management remains open laminotomy with discectomy using loupe magnification (7,16). I perform the approach unilaterally if the symptoms are unilateral. If the patient has a central herniation with bilateral symptoms, I use a bilateral approach with bilateral removal of the disc nucleus. If a massive extruded disc is apparent on imaging studies, a hemilaminectomy may be necessary to provide sufficient longitudinal decompression to be able to safely mobilize the affected nerve root or thecal sac.

In the patient who demonstrates a far lateral or extradiraminal disc herniation, there are two options. An intervening hemilaminectomy may be performed so that the lateral herniation can be clearly visualized between the exiting nerve root above and the exiting nerve root below (15). Thus, for a far lateral disc herniation at L4–L5, expose both the L4 and the L5 nerve roots. Some surgeons prefer an extraforaminal approach (21). In this technique, make an incision lateral to the midline in the region of the transverse processes and facet joints. Carry the dissection through the intertransverse muscles and ligament to expose the lateral disc and exiting nerve root. Gain adequate exposure to understand the pathologic process clearly because the nerve root may be displaced from the normal course (3).

Microdiscectomy has been touted by several authors, most notably McCulloch and Young (12), who have written an entire text dealing with the nuances of this technique. Although lumbar microdiscectomy remains an appropriate technique to remove a lumbar disc herniation, I continue to prefer the open laminectomy approach with loupe magnification. Potential benefits of lumbar microdiscectomy would include a smaller incision, more focused lighting, and not wearing loupes and a fiberoptic headlight. Disadvantages include a higher incidence of dural tears and a more limited exposure, which might contribute to overlooking foraminal stenosis. Length of stay, blood loss, and time to full recovery are not different between the two procedures. I have no objection to these techniques but prefer the open-loupe technique. Our patients do not require blood transfusions. Our average hospital stay has been reduced to a 23-hour admission for the majority of patients with primary lumbar disc herniations.

Percutaneous techniques for lumbar disc removal are of interest and deserve our continued study to determine their usefulness once more clinical outcome studies are reported by noninventors. Kambin and Zhou (8) have demonstrated the clinical feasibility of a percutaneous approach by being able to remove the herniated portion of the disc and visually freeing the nerve root. This was a clear advance over the original automated percutaneous approach, which removed the central disc without addressing the posterolateral herniation. Revel et al. (15) demonstrated automated percutaneous lumbar discectomy to be ineffective in a randomized clinical trial. Treatment was considered successful in 61% of the 72 patients in the chymopapain group, with 44% of the 69 patients in the percutaneous discectomy group. At 1 year, overall success rates were 66% in the chemonucleolysis group and 37% in the automated percutaneous group. Within 6 months of treatment, 7% of the patients in the chemonucleolysis group and 33% in the discectomy group underwent subsequent open surgery. Although complication rates were low, 42% of the chemonucleolysis group continued to complain of significant low back pain.

More recently, Foley and Smith (41) have described the MicroEndoscopic Discectomy (MED) system, which seems appropriately designed for patients with a soft herniation in close relationship to the nerve root. The visualization and lighting are superb. Before widespread endorsement, however, further clinical study is required to ascertain the indications, contraindications, and complications.

HINTS AND TRICKS

The extent of the exposure depends on a number of factors: patient size, size and location of the lumbar herniation, and patient age. For a patient who is in excellent health and good physical condition, I recommend a unilateral approach. Place a small vertical incision over the appropriate vertebral interspace and perform only unilateral paraspinal stripping. Another option is to strip the paraspinal muscles bilaterally but to perform only a unilateral laminotomy. An older patient with significant degenerative changes may require bilateral stripping of the paraspinal muscles in addition to partial resection of the adjacent spinous processes. A patient with a large herniation and a neurologic deficit may require bilateral paraspinal stripping plus a partial or complete laminectomy to gain sufficient visualization to safely remove the herniation and address any additional neurologic injury. No study has shown any adverse outcomes with a more generous exposure, so I believe that it is always better to err on the side of too generous rather than too small an approach. Greater retraction may be required when attempting to remove a large disc herniation through a small exposure. The technique that is illustrated describes a more generous exposure to illustrate better the anatomic details for an axillary lumbar disc herniation. A range of options exists regarding the extent of the exposure, depending on the above-mentioned parameters.

Chemonucleolysis with chymopapain continues to be used sparingly in various centers around the world, but few centers employ this technique in the United States. Although the concept makes some sense, the enzyme uses the central nucleus as the primary substrate without necessarily affecting the protruded portion of the disc. In addition, an enzymatic reaction is difficult to standardize with a set dosage because the composition of the substrate varies widely among patients. For example, the ratio of collagen to nucleus pulposus varies considerably among different age groups. Finally, as noted in the Rand (15) study, only 66% of the patients improved using chymopapain as compared with 85% to 90% in open discectomy (19).

Chemonucleolysis with chymopapain continues to be used sparingly in various centers around the world, but few centers employ this technique in the United States. Although the concept makes some sense, the enzyme uses the central nucleus as the primary substrate without necessarily affecting the protruded portion of the disc. In addition, an enzymatic reaction is difficult to standardize with a set dosage because the composition of the substrate varies widely among patients. For example, the ratio of collagen to nucleus pulposus varies considerably among different age groups. Finally, as noted in the Rand (15) study, only 66% of the patients improved using chymopapain as compared with 85% to 90% in open discectomy (19).

SURGICAL TECHNIQUES

I perform all lumbar disc procedures under general inhalation anesthesia. Once anesthesia has been administered, place the patient prone on a Jackson table with slight hip flexion. This table enhances intraoperative positioning by accommodating a wide range of patient sizes. The abdominal viscera hang free without pressure on the venous plexus. The knees are well supported, and the lumbar spine can be flexed adequately. Transient paraparesthesias in the lateral femoral cutaneous nerve distribution are common postoperatively. In addition, some patients complain of mild postoperative discomfort over the greater trochanter. To prevent irritation of the brachial plexus, the arms must not be elevated excessively in relation to the trunk.

As an example, I describe the approach to the right L4–L5 disc level for the treatment of L5 radiculopathy.

-  Once the patient is properly positioned and carefully checked for pressure areas, especially the ears, prepare and drape the lower back in sterile fashion.
-  Palpate the iliac crests to locate the suspected L4–L5 level.
-  Compare the clinically observed level with preoperative radiographs, and label the level with a marking pencil.
-  Make a vertical midline incision over the appropriate spinous processes.
After the skin incision is made, complete the remaining portion of the dissection to the bony lamina using electrocautery. Extend the dissection to the lumbodorsal fascia. Identify the spinous processes of L-4 and L-5, and use the cautery unit to incise the fascia directly over the spinous processes. Use pickups to apply tension or a Cobb elevator as a gentle retractor. Dissect the fascia away from the spinous processes of L4–L5 and the inferior portion of L-3. By using Cobb elevators, carefully strip the paraspinous muscles from the spinous process to the lamina. Take care to maintain a subperiosteal approach. Blood loss is markedly reduced by avoiding the muscle envelope. Once the periosteum is stripped, insert a self-retaining retractor. Irrigate the wound and clearly identify the interlaminar space of L4–L5. Place a towel clip through a spinous process, and obtain a lateral radiograph to confirm the level. Once you are satisfied that you are operating at the proper level, continue dissection by partially resecting the inferior portion of the L-4 spinous process and the superior portion of the L-5 spinous process:

1. Examine the interlaminar space. With a Penfield 1 elevator, strip the ligamentum flavum from the inferior and anterior surface of the lamina of L-4 (Fig. 144.1).

2. Use a Penfield 1 elevator or curved curet to remove the ligamentum flavum from the anteroinferior surface of the lamina of L4.

3. Use a Harper 45 rongeur to excise part of the middle portion of the L-4 lamina (Fig. 144.2).

4. Carry the dissection cephalad until the midline raphe of the ligamentum flavum can be identified.
5. Insert a Penfield 3 elevator in the midline from proximal to distal immediately anterior to the ligamentum flavum (Fig. 144.3). Using a #15 blade knife, divide the ligamentum flavum in the midline.

6. Pass a Penfield 3 elevator from proximal to distal, and divide the ligamentum flavum on top of the elevator to minimize the possibility of injury to the dura.

7. Carry the dissection laterally toward the lateral recess, again using the Penfield 1 or Penfield 3 elevator to protect the underlying dura (Fig. 144.4). Dissection can be accomplished using either a scalpel, curets, or a rongeur with a 45° angle.

8. Once the bulk of the ligamentum flavum has been removed, examine the epidural fat and dura to determine the degree of lateral wall dissection necessary to identify and retract the displaced nerve root safely. In this chapter, I have chosen to depict a less common form of disc herniation to emphasize the pitfalls of root injury (Fig. 144.5). When the disc herniation is medial to the root, the lateral portion of the dura may be misinterpreted as being the lateral border of the nerve root. Such a misinterpretation can result in division of the nerve root or at least injury to the nerve root. Take extreme care to identify the nerve root.
Figure 144.5. Expose the contents of the vertebral canal after resection of the ligamentum flavum from the right side and after lateral wall resection using an upbiting rongeur with a 45° angle. A disc herniation medial to the nerve root was illustrated intentionally to emphasize the point that the surgeon can mistake the lateral border of the dura for the lateral border of the nerve root. The nerve root must be clearly visualized.

- Resection of the lateral wall of the spinal canal using a rongeur with a 45° angle is necessary in most cases.
- Once the nerve root is identified and the disc herniation is visualized, remove a portion of the herniation. Then medially displace the root and excise the remaining portion of the displaced disc (Fig. 144.6).

Figure 144.6. Gently elevate the nerve root with a Freer elevator and a Penfield 4 elevator, and retract it medially over the displaced disc tissue. A Love root retractor can be used as illustrated to displace the root dura medially. Then remove the extruded disc with a small pituitary rongeur.

- A disc herniation is categorized as being extruded when the annulus is disrupted, and the herniated portion of the disc is categorized as being protruded when the annulus is intact but eccentrically displaced. The term sequestered is applied to a free fragment of intervertebral disc lying in the spinal canal with no defect evident in the annulus fibrosus. Seventy-five percent of lumbar disc herniations are of the extruded variety, whereas sequestered disc fragments are far less common (less than 5%).
- Dissect from the medial portion of the dura laterally, using a Penfield 4 elevator in the dominant hand and a Freer elevator in the other hand. Take extreme care to identify the displaced nerve root. Use of surgical loupes with 2.5 magnification and a fiberoptic headlight is essential for optimal visualization in this operation. Once the nerve can be displaced medially, insert a Love root retractor to displace the nerve root and dura gently medially, so that the extruded disc herniation can be excised (Fig. 144.6). A sharp incision into the annulus is seldom necessary because the pseudomembrane overlying an extruded disc can nearly always be dissected using a Penfield 4 elevator. In protruded disc herniation, however, the annulus must be incised.
- Once the disc has been removed, free the nerve root of tension and carefully inspect the neural foramina. The nerve root should be able to be displaced at least 1 cm medially (Fig. 144.7).

Figure 144.7. After disc removal, it should be easy to displace the involved nerve root 1 cm medially. Should the root remain fixed, additional exploration of the foramina and the vertebral canal is necessary.

- Take care to ensure that no disc material is present between the annulus and the posterior longitudinal ligament.
- Once the disc has been excised, irrigate the wound and place an interposition membrane of Gelfoam or fat over the laminotomy. At present, I prefer to use Gelfoam (Fig. 144.8).

Figure 144.8. An interposition membrane of Gelfoam; many surgeons prefer fat grafts.

- Then close the wound in layers. Use figure-8 sutures to achieve watertight closure of the fascia; I prefer subcuticular stitches for the skin.
- Apply a dry, sterile bandage.
- Gently straighten and rotate the patient onto the stretcher for extubation. Following extubation, take the patient to the recovery room. Blood transfusion is seldom necessary for a primary lumbar discectomy because blood loss usually averages less than 100 ml.

I have used this technique successfully for the past 15 years with no incidence of recurrent disc herniation over that reported by others (2%).

FAR LATERAL AND INTRAFORAMINAL DISCS

Far lateral and intraforaminal disc lesions cannot be easily removed through a midline approach (Fig. 144.9). Although taking down the entire facet is one alternative
advocated by some (1), the extraforaminal approach has been advocated by Wiltse (21, 22). The proponents of going from the midline through the facets suggest that instability is not a subsequent problem and believe the nerve root can be more easily identified. Furthermore, they believe the surgeon can have greater confidence of complete decompression. However, many do not share this view.

Figure 144.9. Far lateral disc lesion. Note the relationship of the disc to the transverse processes.

The paramedian approach popularized by Wiltse (21,22) is a muscle-splitting approach.

- Make the incision 5 cm from the midline, followed by blunt dissection of the paraspinal muscles (Fig. 144.10).

Figure 144.10. The annulus is incised, the nerve root is retracted laterally, and the disc is removed with a pituitary rongeur.

- At this point, take radiographs to verify the level and clear the transverse processes of soft tissues.
- Enter the intertransverse ligaments and fascia with a knife or curet, then remove those structures between the transverse processes.
- Identify the nerve, which is usually 2 to 4 mm anterior to the fascia and directed at a 45° angle (Fig. 144.11).

Figure 144.11. Nerve identified and retracted at a 45° angle.

- Follow the nerve medially and identify the disc.
- If a free fragment is present, remove it. If only a bulge is present, incise the annulus and remove easily identifiable fragments. When the nerve root is easily mobile, sufficient disc has been removed.
- If the lesion is extraforaminal, take down a portion of the facet laterally to expose the nerve root canal. McCulloch and Young (12) point out, however, that this procedure is rarely necessary because of the usual anatomic location of these lesions.
- Closure in both instances is routine, using a free fat graft or Gelfoam to cover the nerve.

POSTOPERATIVE CARE AND REHABILITATION

In most patients, the preoperative radicular symptoms are improved when they awaken in the recovery room. On the evening of surgery, the patient is permitted to stand. By the first postoperative day, the patient is allowed to ambulate. If a dural leak occurs, ambulation is delayed by 24 to 48 hours. An abdominal binder is used for 4 weeks as partial protection for the patient. Rehabilitation is initiated 4 weeks after surgery and continued indefinitely. Patients are advised to maintain ideal weight and to develop good abdominal and trunk extensor muscle tone. Aerobic activity is encouraged and is initiated 4 weeks following surgery. Patients are discharged from follow-up approximately 12 months after surgery.

PITFALLS AND COMPLICATIONS

The primary consideration is the selection of appropriate patients for surgical repair of lumbar disc herniations. The use of an objective method to accomplish this, as described in this chapter, will lessen the incidence of negative explorations (19), which is less than 2% in my experience. Although technical errors infrequently account for persistent pain after surgery, such errors invariably compromise the outcome. In a patient with established disc herniation, exploration at the wrong intervertebral level will not benefit the patient (10). Avoid this mistake by taking an intraoperative radiograph to confirm the appropriate level. If a disc herniation is not found, consider exploring additional levels after an intraoperative radiograph to confirm the proper level. Explorations at the wrong level are more common in patients who have transitional lumbar vertebrae.

Poor technique can prolong postoperative pain. Because excessive traction of neural tissue can cause irreversible nerve damage, use loupe magnification and fiberoptic lighting. These technologies have done much to minimize injury to neural tissue. Likewise, the use of an interpositional membrane (either free fat grafts or Gelfoam) at the completion of surgical exploration may minimize long-term perineural scar formation. Presently, newer antiadhesion barriers are being investigated in the United States. Experience in Europe has suggested that such barriers may lessen scarring within the spinal canal and perhaps even enhance clinical outcome. Additional evaluations are necessary to support these early but exciting assertions scientifically.

Technical errors can also result when the surgeon fails to detect a fragment of disc tissue that has migrated from the level of herniation, either cephalad in the canal or laterally into the extraforaminal area, trapping nerve roots (10). Because the only patients who should undergo surgery are those with objective findings, explore the canal thoroughly if no specific pathologic changes are encountered at the suspected level. Because the nerve root should be able to be displaced easily for a distance of approximately 1 cm medially, a nerve root that is tight in the canal and cannot be displaced suggests either a sequestered fragment along the nerve root or a stenotic lateral recess (10). Gently palpate the cauda equina to ensure that an intradural disc herniation is not present. Although a neoplasm involving the neural elements of the lumbar spine is always a possibility, it is distinctly uncommon. The most likely neoplastic lesion encountered in the lumbar vertebral canal is a
metastatic extradural lesion.

Hemostasis is essential in lumbar disc surgery. With proper technique, blood loss should be minimal, rarely exceeding 150 ml. Generally, epidural bleeding is easily controlled with bipolar coagulation, packing, or both.

Always be prepared to expand the surgical exposure. A straightforward unilateral lumbar disc herniation rarely requires a complete laminectomy; however, when the surgical findings do not explain the preoperative symptoms, more open exposure is necessary.

Inadequate exposure can also present problems. Identify the dura and the nerve root, and expose the lateral wall adequately before examining the nerve root. Attempting to extract a large, extruded fragment through a small incision may traumatize the involved nerve root unnecessarily.

This point is especially important when dealing with a patient who presents with a cauda equina syndrome or a large central herniation without neurologic involvement. In these situations, remove the ligamentum flavum on both sides of the spine. Because the dura matter will be displaced posteriorly, a careful dissection is essential to avoid injury. A laminectomy may be the most appropriate exposure to ensure adequate visualization of the thecal sac and the exiting nerve roots on both sides. Often, the most appropriate beginning may be to perform an annulotomy and discectomy on the side with least herniation and to provide easier access to the root under maximal tension.

In patients older than 40 years of age, exploration of the neural canal must include a careful assessment of the lateral recess to interpret pathologic changes accurately. Performing a discectomy in a patient who also has lateral entrapment of the nerve root will not reduce the patient's symptoms. Careful probing of the neural foramina at the completion of the lumbar discectomy will locate the narrowing of the neural foramina. If stenosis of the lateral recess is the only manifestation, lumbar discectomy may not be necessary.

As with any surgical procedure, a list of potential complications that might occur would be exhaustive. Dural tears may occur during a lumbar discectomy. Such tears are more common in patients who undergo surgery for spinal stenosis or revision procedures. I recommend primary repair of dural tears with 5-0 Dermalon. Injuries to the iliac arteries and veins and viscera, including any structure from the appendix to the ureter, have been reported in association with a lumbar discectomy (15). Errors in diagnosis may occur. The patient may have symptoms suggestive of a lumbar disc herniation, which may, in fact, be related to intra-abdominal pathologic processes such as an aneurysm or a malignancy. Minimize these unusual complications by performing a thorough diagnostic assessment and decision analysis before a decision to operate on the spine. With proper patient selection and careful operative technique, lumbar disc surgery is highly successful and yields gratifying results for both the patient and the surgeon.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

The term degenerative disc disease (DDD) has been used to describe a wide variety of morphologic and radiographic changes in the adult lumbosacral spine. The North American Spine Society Consensus Committee on Nomenclature defined disc degeneration as follows:

Changes in a disc characterized by desiccation, fibrosis, or cleft formation in the nucleus; fissuring or mucinous degeneration of the annulus; defects and sclerosis of the endplates; and/or osteophytes at the vertebral apophysis.

The committee noted, “The term degeneration does not imply an etiology. Depending on age, degree, and type of change... the changes of disc degeneration may be clinically insignificant.” Degenerative disc disease, on the other hand, is broadly defined as “a clinical syndrome characterized by manifestations of disc degeneration and symptoms thought to be related to those changes.” The authors point out that “causal connections between degenerative changes and clinical symptoms are often difficult clinical distinctions.”

In this chapter, degenerative disc disease refers to a continuum of nonradicular, mechanical pain disorders of presumably degenerative origin. Specifically excluded are those disc pathologies with neurologic impingement, such as disc displacement, spinal stenosis, and deforming degenerative conditions, such as degenerative scoliosis and spondylolisthesis.

Degenerative disc disease as a clinical entity remains controversial for five principal reasons:

1. A confusing and contradictory nomenclature
2. The similarity of “pathologic” changes to those of normal aging
3. The difficulty in accurately identifying the source of pain
4. Our limited understanding of the etiology and natural history of this process
5. Historically low success rates from surgical intervention for patients with DDD

PATHOPHYSIOLOGY AND PATHOMECHANICS

BACK PAIN

The social impact and suffering that results from back pain cannot be overestimated. With a lifetime incidence of 60% to 80%, low back pain (LBP) generates at least 15 million office visits per year (23). In fact, low back complaints are the leading compensable cause of injury in the workplace. In the United States, $24 billion a year is spent on the evaluation and direct management of patients with back pain. Indirect costs include work and productivity losses, and they account for an additional $27 billion annually (28).

Typically, back pain has a benign course. Within 3 months of the onset of symptoms, 95% of patients return to their previous employment. The 5% of patients with residual symptoms after 3 months, however, incur 85% of the costs. Moreover, the probability of returning to work falls with increasing duration of disability. After 2 years off work, less than 2% will return. Therefore, the early detection of those patients in whom LBP is more likely to become chronic would be of tremendous clinical and social benefit.

Adult LBP can arbitrarily be divided into five categories:

1. Refrained back pain
2. LBP with radiculopathy or myelopathy
3. LBP with deformity, such as scoliosis, kyphosis, or spondylolisthesis
4. LBP in the context of fractures, tumors, or infections
5. Mechanical LBP without the features already noted

Before focusing on the spine and its related structures, consider other potential sources of referred pain. Included in the first LBP group are intra-abdominal and retroperitoneal pathologies such as abdominal aortic aneurysm and endometriosis. In groups 2 through 4, symptoms more readily correlate with evident spinal
pathology; as a result, treatment of these patients is satisfying and, overall, associated with good results.

The fifth group, patients with mechanical LBP only, includes several benign conditions, most likely representing ligamentous and muscular strain, mechanical stress from poor posture, or facet joint irritation. More chronic and disabling degenerative disc conditions, however, are included as well. In these patients, uncertain identification of the pain generator is associated with vague diagnostic groupings and failed surgical management. Included among these is DDD.

The multiple and synonymous terminology reflects an incomplete understanding of the pathophysiology and natural history of DDD. Moreover, because the “pathoanatomic” changes noted in DDD do not qualitatively differ from those of normal aging, the appropriateness of the appellation disease is intensely debated.

NOCICEPTION IN THE DISC

It is theorized that in DDD, pain arises in the disc. Historically, while the lumbar facets, posterior longitudinal ligament, dura, dorsal root ganglion, and myofascial structures of the lumbar spine have been recognized as pain-generating structures, the disc was felt to be aneural. More recently, however, nociceptive fibers have been identified in the outer annulus.

In one study, pain was generated by applying pressure to the disc during operations under local anesthesia. In another study, back pain resolved with procaine injection into the disc. Kuslich et al. used a progressive local anesthetic technique to gauge pain response in different tissues in 193 consecutive laminectomies. Stimulation via blunt probe or unipolar electrocautery on the facet cartilage and synovium never caused pain. Also, no pain followed stimulation of the lamina, spinous process, ligamentum flavum, lumbar fascia, and uncompressed roots. Stimulation of the facet capsule, however, was associated with sharp, localized pain in 30% of patients. This pain did not match the patient’s preoperative symptoms. Stimulation of a compressed root resulted in sciatic pain in 79%. Finally, LBP similar to preoperative symptoms was noted in 70% of patients after stimulation of the posterior annulus or posterior longitudinal ligament (PLL). Local anesthetic injection obliterated the pain.

Nociceptive free nerve endings of the recurrent sinuvertebral nerve most likely carry these impulses. The sinuvertebral nerve, first described by Von Luschka, consists of a postganglionic derivative of rami communicantes that branches into segments. These segments ascend and descend into one or more adjacent levels. The branches accompany the venous plexus into the vertebral endplates and terminate in nociceptive free nerve endings in both the PLL and outer lamina of the annulus. In histometric studies, the outer third of the annulus has been found to contain nerve endings with nociceptive neurotransmitters [substance P, calcitonin, vasoactive intestinal peptide (VIP)]. Further, nociceptive fibers may grow into diseased discs. Theoretically, a small tear of the outer annulus may cause pain, even with a normal nucleus pulposus.

Disc degeneration may indirectly stimulate pain receptors elsewhere. Disc height collapse may produce nociceptive signals from the facet mechanoreceptors by abnormal loading. Such mechanical derangement has been associated with abnormal intervertebral motion and has been termed lumbar segmental instability.

A degenerated disc may also indirectly cause pain by extrusion of nuclear material, a source of neural irritation and inflammation. The potential sources of pain in the lumbar spine are illustrated in Figure 145.2.

NORMAL AGE-RELATED CHANGES IN THE DISC

During an individual’s lifetime, intervertebral disc composition changes greatly. Given that certain degenerative phenomena may lead to pain, it is necessary to have a clear understanding of what changes constitute normal degeneration.

At birth, the disc surface area is 50% nucleus pulposus (NP) and 50% annulus. The notochordal cells of the NP are gradually replaced by chondrocytes throughout the early teenage years. This replacement is associated with annular thickening. The demarcation between the annulus and the nucleus becomes less distinct. The older NP has a higher collagen content with more structured fibers. In these fibers, the ratio of type II to type I collagen increases.

Figure 145.1. The course of the sinuvertebral nerve. A: The sinuvertebral nerve shown on a cutaway drawing. B: The branches of the invertebral nerve shown on a lateral view of an intact spine.

Figure 145.2. Various potential pain generators in the lumbar spine.
Proteoglycan metabolism changes with age as well. Chondroitin-4-sulfate and chondroitin-6-sulfate concentrations decrease, and the ratio of keratin sulfate to chondroitin sulfate increases. Keratin sulfate has a smaller hydrophilic potential and a reduced tendency to form stable aggregates with hyaluronic acid. Dehydration, in turn, decreases the disc’s resistance to axial loading (50).

As desiccation continues, clefts can be identified that originate in the central portion of the dehydrated NP. One hypothesis holds that these clefts eventually migrate toward the peripheral annulus and endplate and cause tears. Annular tears are classified by Vernon-Roberts (65) as peripheral, circumferential, and radiating. Circumferential and radiating tears are associated with degenerative changes in the endplate and NP.

Circumferential tears lead to further nuclear degeneration in animal models (47,54). Vascular ingrowth may also mark degenerated and herniated discal tissues (41).

At present, there is no clear boundary between these aging changes and disc degeneration. While some authors claim a quantitative if not qualitative difference between aged and degenerated discs, all discs degenerate with age. Miller et al. (65) reported evidence of disc degeneration by the age of 50 in 90% of 600 autopsy specimens. Holt (39) found evidence of disc degeneration on the plain radiographs of 80% of adults studied, although 53% had no history of LBP.

**ETIOLOGY**

While it appears that all intervertebral discs degenerate with age, the degree and rate of this degeneration vary significantly from individual to individual. The underlying reasons for this variability are only partly known.

The Hirsh theory of disc degeneration holds that insufficient nutrition, impaired waste transport, and traumatic mechanical factors combine with a genetic and hormonal proclivity to cause desiccation and annular tearing. Severe degeneration is associated with increased lactate metabolism, decreased pH, accumulation of proteolytic enzymes, and chondrocyte necrosis (Fig. 145.4) (37).

Various clinical factors have been implicated in precocious degeneration. Smoking and a familial tendency toward degeneration have long been established as contributing factors (68). Twins demonstrate similar degeneration patterns (3). In one study of 15-year-olds, LBP, decreased activity, and decreased spinal range of motion predicted later DDD (65). Anatomically, no association between DDD and facet tropism can be demonstrated (6). The endplate irregularities of thoracolumbar Scheuermann’s disease, however, may be related to DDD (35).

**PATHOPHYSIOLOGY OF DDD**

If disc degeneration is a programmed, physiologic phenomenon influenced by heredity and environment, it is incumbent upon the clinician to ascertain when these changes constitute a disease. Benign age-related phenomena have been differentiated from pathologic phenomena on the basis of three factors: impaired function, structural changes, and an association with pain.

Yong-Hing and Kirkaldy-Willis (66) described a three-joint complex in the spinal column, with the disc anteriorly and the two facet joints posteriorly. They theorized that benign microscopic alterations progress to pathologic degeneration in stages. In this way, circumferential annular tears progress to radial tears. Radial tears, in turn, engender further disc degeneration or frank disc herniation. The ensuing loss of disc height alters facet joint mechanics, and facet cartilage disruption or destruction may take place. Coincidentally, the decrease in the intervertebral height causes buckling of the ligamentum flavum and facet overriding or enlargement. These changes may, singly or in combination, cause narrowing of the neuroforaminal and central canals. So, while disc degeneration manifests as mechanical LBP in some patients, others will experience neurologic claudication or radiculopathy from frank disc herniation (Figs. 145.5, 145.6).

**Figure 145.3.** Schematic of basic intervertebral disc anatomy.

**Figure 145.4.** The role of nutritional deficiency in the etiology of discogenic back pain. With advancing age, disc cells diminish in number and distribution and undergo metabolic variations. As a consequence, disc nutrition diminishes. These changes are accelerated by systemic factors such as overall nutritional status, smoking, motion, and endplate or disc calcification. Ultimately, cell death, increased enzyme activity, molecular breakdown, and instability ensue.

**Figure 145.5.** The Kirkaldy-Willis (66) states of lumbar degeneration, including (left side) the events that occur in the facets and (right side) intervertebral discs and associated syndromes.
Yong-Hing and Kirkaldy-Willis (86) then proposed three stages of degeneration of the intervertebral disc.

I. Microscopic alterations of disc consistent with aging
II. Increased spinal mobility
III. Stabilization of the functional spinal unit (discs anterior and facets posteriorly)

Vernon-Roberts (20) showed that many of these changes are present in nearly all middle-aged people and are not necessarily associated with back pain. Thus, the issue of when degenerative changes represent a disease remains unresolved. While data are lacking, it has been suggested that younger patients with relatively precocious disc degeneration do not tolerate these changes as well as older adults. Whether this perceived difference stems from higher functional demands or from a subtle difference in disc mechanics is not known. It is reasonable, however, to identify DDD as a chronic, mechanical LBP syndrome associated with changes in the structural and functional integrity of one or more intervertebral discs.

TYPES OF DDD

At present, DDD can be characterized by one of several associated terms, listed in Table 145.1. While some authors use these terms to refer to the same global discogenic pain syndrome, others view them as a means to differentiate among subgroups of patients. The divisiveness and misapplication of nomenclature further confuses any evidence-based appraisal of DDD, and its incidence, pathophysiology, and natural history.

Table 145.1. Named Discogenic Disorders

Three subtypes may be identified as points in a continuum. First, internal disc disruption (IDD) refers to a painful annular tear in the absence of bony changes or disc height loss. As such, IDD must not be confused with disc protrusions, which are normal hydrodynamic findings (5).

Next, lumbar spondylosis (LS) refers to mechanical back pain in association with disc height loss, sclerosis, and osteophyte formation. LS is the most frequently described form of DDD, and it is the entity most authors are describing when they use the more global term DDD.

Finally, lumbar segment instability (LSI), which represents a progressive relaxation of facet capsules and ligamentous restraints, occurs in the context of chronically compromised disc biomechanics. White and Panjabi (83) define lumbar instability as more than 4.5 mm of translation, 15° to 25° of angular motion between adjacent segments on flexion-extension radiographs, or both (Fig. 145.7). It is not clear, however, that the chronic increase in intervertebral motion seen in degenerative lumbar diseases may be mechanically equated with traumatic spinal instability. Therefore, some authors classify this abnormality with degenerative spondylolisthesis and degenerative scoliosis, which have a similar pathogenesis. Others feel that all the subtypes of DDD represent a painful “microinstability” of the motion segment (48).

NATURAL HISTORY OF DDD

The critical question of why most degenerated discs are asymptomatic remains to be answered. Even in those patients with degenerative changes, severe back pain, and positive discography, pain may spontaneously improve. In one series, 25 patients who had not had surgery were positive on a single-level discogram. When they were evaluated after an average of 4.9 years, 69% had improvement without surgery (70). Of the 32% who were unimproved, 69.7% had an underlying psychiatric diagnosis. In the absence of a more complete understanding of the natural history of this disorder, appropriate evaluation of surgical outcomes is extremely difficult.

In summary, while knowledge of the benign degeneration of the aging spine continues to grow, surprisingly little is known about disc degeneration as a disease process.
Table 145.2. What We Do Not Know about Disc Degeneration as a Disease

**EVALUATION AND IMAGING**

**HISTORY**

When evaluating a patient with chronic LBP, DDD remains a diagnosis of exclusion. A thorough history and physical examination are mandatory.

In patients with “red flags” such as very young or old age, nonmechanical pain, constitutional symptoms, and trauma, perform a thorough radiologic and serologic evaluation for infection, tumor, and fractures (Table 145.3). Other important considerations include intra-abdominal and intrapelvic pathology. Posterior penetrating ulcers, pancreatitis, renal disease, abdominal aortic aneurysm, and endometriosis are all known causes of severe, referred pain to the back.

Table 145.3. Historical Elements Requiring Thorough Evaluation (“Red Flags”)

Pay careful attention to historical clues as well as to significant social and psychological issues. Ask specific questions regarding drug and alcohol intake, mood, sleep disturbance, pending litigation, and job satisfaction.

In patients with pain of degenerative etiology, first exclude those with radicular or myelopathic signs and symptoms. Similarly, the evaluation of patients with significant thoracolumbar deformities such as scoliosis, hyperlordosis, and kyphosis is considered elsewhere (see Chapter 153, Chapter 155, Chapter 156, Chapter 159, Chapter 160, and Chapter 161). For example, spondylolisthesis, another disorder of genetic and environmental stress, is the most common structural abnormality in the adult spine (see Chapter 162). Spondylolisthesis is related to LBP in 5% of the population (21).

The evaluation of the remaining group of patients with isolated, mechanical LBP is challenging. The difficulty in identifying a specific pain generator accounts for the fact that only 15% of patients are given a definitive diagnosis. Physically and radiographically abnormal structures may not cause symptoms. On the other hand, grossly and radiographically normal structures may be associated with severe pain in certain individuals.

Muscular etiologies account for the vast majority of patients reporting acute LBP. Patients with myofascial pain are especially difficult to distinguish from those with “discogenic pain” when radiographic signs of disc degeneration are present. However, myofascial pain tends to have an acute onset and a relatively brief duration. The pain is localized to a specific paraspinal area, and muscle spasm is evident. In most cases, while some DDD patients identify a specific, traumatic event (such as bending, lifting, or twisting) with symptom onset, their pain is midline and does not resolve but rather worsens over time.

The pain described by patients with DDD is mechanical in that it is aggravated by activity, particularly flexion. Relative rest temporarily ameliorates symptoms. Patients with lumbar segmental instability may complain of a catch with flexion and extension (Fig. 145.8). DDD patients may also report having difficulty when getting up from a chair. In an attempt to splint the back, some will use upper extremity leverage, pressing their arms against their thighs, when arising.

Figure 145.8. A suggested algorithm for the evaluation of discogenic back pain. DDD, degenerative disc disease; F/E, Flexion/Extension; SX, symptomatic.

Pain related to DDD may predate or postdate an episode of sciatica. Often, DDD patients report having had prior discectomy or chymopapain injections (20). Further, the disc collapse associated with LS may result in foraminal stenosis and mild radiculopathies (66). Other patients followed for axial spinal pain will later present with acute radicular complaints and imaging studies consistent with disc herniation. Diagnosis and treatment for these patients is discussed in Chapter 144.

Degenerative discs may be associated with referred, sclerotomal pain to the buttocks and posterior thigh. However, it is very difficult or impossible to localize the symptomatic disc level on the basis of history or physical exam alone.

**PHYSICAL EXAMINATION**
The examination of DDD patients is generally nonspecific. These patients exhibit no point tenderness or paraspinal spasms. They often report pain or difficulty with flexion and rotation maneuvers of the spine, however. Normal neurologic findings including sensory, motor, and reflex exams are expected. Particular attention must be paid to Waddell’s signs (Table 145.4) [79], which suggest psychological overlay.

Table 145.4. Waddell’s Nonorganic Physical Signs

Moreover, unexpected findings on physical examination such as anal sphincter laxity or major muscle weakness should be construed as red flags and investigated accordingly.

PLAIN RADIOGRAPHY

The ubiquity of painless LS limits the specificity of plain radiography in DDD. In the absence of red flags, radiographs are indicated only after a trial of symptomatic treatment. In patients failing to improve with these modalities, begin radiologic assessment with plain anteroposterior (AP) and lateral views of the lumbosacral spine. Oblique views and a lateral L5–S1 cone-down view are often helpful. The principal purpose of these studies in the early management of mechanical back pain is to exclude spondylolisthesis and the less benign entities mentioned previously.

Patients with internal disc derangement will have no plain radiographic changes. The cardinal findings of LS are endplate sclerosis and loss of disc space. Radiographs may also show a loss of lordosis, subluxations, vacuum phenomenon, and osteophytes (Fig. 145.9). Radiography, however, can be misleading: Frymoyer et al. [24] showed that signs suggestive of disc degeneration were present in 90% of adults studied, whereas 53% had no history of LBP (Table 145.5).

Figure 145.9. Plain radiographic findings of DDD: disc space loss, endplate sclerosis, and osteocyte formation.

Table 145.5. Plain Radiographic Findings of DDD

It should be noted that the presence of nitrogen gas bubbles (the vacuum phenomenon) in degenerative discs probably excludes the diagnosis of discitis, as infection by gas-forming organisms are exceedingly rare.

In patients with normal findings on static radiography, obtain flexion–extension radiographs to exclude subtle instability patterns. Relatively subtly increased intervertebral motion can be associated with pain. In these patients, discography may be useful to establish a pain generator. Some authors assign no clinical importance to lumbar segmental motion [24,32].

Radionuclide bone scans have only a minor role in the evaluation of disc degeneration by excluding other suspected pathologic processes, such as tumor, infection, or spondylolysis. Computed tomography (CT) may demonstrate degenerative changes in the lumbar spine, but is not particularly useful in the evaluation of patients with DDD.

MAGNETIC RESONANCE IMAGING

In the evaluation of DDD, magnetic resonance imaging (MRI) is the most commonly employed imaging modality. In that MRI can directly measure water content of the disc, it is the only imaging technique that can detect biochemical changes in the nucleus (56,61). The normal, hydrated NP has an increased proton signal on T2 images. With increasing desiccation, this signal blends with that of the surrounding annulus. With further degeneration, a dark, isointense signal may be seen on T2 (Fig. 145.10, Fig. 145.11). An increased T2 signal may be noted in some areas, where it is thought to represent free fluid in annular tears and fissures (87). April and Bogduk [1] described a high-intensity zone (HIZ) representing a tear of the outer annulus. In their study, these HIZ lesions were associated with painful, concordant discography. Subsequent reports as to the significance of these lesions have been mixed [64].
Aside from the discs themselves, changes in endplate morphology adjacent to degenerating discs may have clinical significance. These changes were first described by Modic et al. and can be divided into three types. Type I reflects an acute disruption and fissuring of endplates, which leads to ingrowth of vascularized fibrous tissue into the adjacent vertebral body marrow. This tissue exhibits a diminished signal on T1 images and increased signal on T2 images.

In chronic degeneration, the hematopoietic (red) peridiscal marrow undergoes fatty degeneration. Here, a type II pattern is exhibited with an increased T1 and an isointense or slightly hyperintense T2 signal. While type II changes tend to remain stable, type I changes have been shown to develop into type II. Type III changes probably reflect extrinsic bone sclerosis as seen on plain radiographs. Dense bone in the vertebral endplates yields a hypointense signal on both T1 and T2 images.

Just as the pathologic changes of disc degeneration are likely to be a normal part of aging, the MRI findings associated with the changes described by Modic and Ross frequently do not correlate with LBP. In 1990, Boden et al. found that MRI evidence of degenerative discs was present in 34% of patients 20–29 years old, and in 93% of patients 60–80 years old.

### DISCOGRAPHY

Although discography is controversial, it represents the only provocative method available to assess patients with a possible discogenic pain generator. In theory, fluid injected into the disc increases endplate pressures. These transferred pressures may cause pain. Abnormal pressure transmission may account for the small subset of patients with normal MRI findings and positive discography. Properly performed, discograms may be able to directly identify a cause-and-effect relationship between radiographic signs of degenerated discs and clinical symptoms of lumbar pain.

Morphologic information is available from the discogram or a postdiscography CT. Abnormal radiographic findings with leakage of dye were seen in 37% of an asymptomatic population, so the study is positive only if the radiographic changes correlate with a concordant pain response. A concordant response requires replication of the patient’s usual pain with injection at the degenerated level, and no pain at adjacent, control levels.

Figure 145.12. Discography at the L3-4, L4-5, and L5–S1 interspaces. Note the normal appearance of the control L3-4 level and the abnormal morphology below.
In one large series, Holt (38), having found that a high percentage of previously asymptomatic volunteers had positive discography, considered the test unreliable. This study was later criticized by Simmons et al. (69), who noted that injections without fluoroscopic guidance often pressurize the sensitive annulus rather than the nucleus. Further, the contrast material used, diatrizoate meglumine, has been found to be irritating and painful. Later, the Holt study was repeated using modern techniques by Walsh et al. (68), who injected a nonionic, water-soluble contrast agent under fluoroscopic guidance. The study was considered positive only if the disc was radiographically abnormal and a concordant pain response reported. A false-positive rate of 0% with a specificity of 100% was noted in 10 asymptomatic volunteers.

Calkoun et al. (6) found that 89% of 137 patients with positive provocative discography had significant and sustained benefit from fusion at the indicated level. Of 20 patients fused without a positive discogram, only 52% enjoyed postoperative pain relief.

Given the overall controversy surrounding discography, it can be expected that recommendations regarding its role in patient assessment also vary. Some report that a negative MRI may miss clinically significant DDD (7). Others report that positive discography in the context of a negative MRI is associated with inferior results after fusion (27).

Schneideman et al. (67) found a high correlation between MRI and discographic findings. They reported on 101 disc levels in 36 patients with LBP of longer than 2 months’ duration. In each patient, both MRI and discography were performed and blindly reviewed by a neuroradiologist. MRI was accurate in predicting discographic disc morphology 99% of the time. Only one disc level with a normal MRI signal had an abnormal discogram. Of 49 levels with decreased signal on MRI, only two were normal on discogram. The authors found that concordant pain with discography was helpful in the assessment of abnormal discs identified by MRI, but they felt that discography was not indicated in the presence of a normal MRI. Simmons et al. (69), on the other hand, found only a 55% correlation between the tests. They wrote that discography is the only dynamic test available for disc evaluation and thus the only study that can determine which abnormal discs are truly symptomatic.

Horton and Daftari (40) found that, in many cases, MRI could not reliably predict or replace discography. They divided the MRI signal of lumbar discs into dark, white, and speckled patterns, and they characterized the posterior annulus as flat, bulged, or torn. Most dark or torn discs demonstrated positive discography, whereas white or flat discs were very likely to be negative on discography. The intermediate MRI patterns had uncertain correlation with discographic findings, however.

At present, we feel that discography should be performed only as a preoperative test in psychologically normal patients with positive MRI findings, and after aggressive, nonsurgical measures have failed. Discography is probably not warranted in patients with single-level changes. In patients with multilevel or equivocal MRI findings, we use a discogram to detect the symptomatic level.

**IMMOBILIZATION TECHNIQUES**

Various braces and supports have been recommended to provide pain relief in DDD (14, 60, 65). The underlying hypothesis is that bracing will simulate effects of fusion by restricting segmental motion. In general, such bracing is not justified, in that the braces most commonly recommended are unreliable in restricting lumbar spinal motion (17, 68). Adequate immobilization of the lower lumbar sacral spine requires a pantaloon brace.

**PSYCHOLOGICAL ASSESSMENT**

Ultimately, the treatment of DDD is directed only at pain, the perception of which is quite variable. Depression and anxiety are quite common in DDD patients and are associated with heightened pain perception (77). Historically, it has been difficult to establish whether the pain preceded the psychological disturbance. However, in a series of 200 patients with chronic back pain, 77% met the American Psychiatric Association’s Diagnostic and Statistical Manual of mental disorders (DSM III-R) lifetime criteria for psychotic illness, and 59% met criteria for current, active psychiatric illness (63). In this study, the authors concluded that psychiatric illness (particularly anxiety and substance abuse disorders) often preceded the onset of back pain.

Indications of somatic fixation on the Minnesota Multiphasic Personality Inventory (MMPI) include abnormal elevations of the hypochondriasis and hysteria scales, above that of the depression scale. On this inventory, somatic fixation tends to be predictive of poor surgical outcomes (68). Patients with low hypochondriasis and hysteria scores had 90% good to excellent results 1 year after surgery, while patients with higher scores had only a 10% rate of good to excellent results (69). Southwick and White (71) reported that patients in the latter category were more likely to have positive discograms at nondegenerated levels.

**SUMMARY OF THE ASSESSMENT STRATEGY**

While certain radiologic findings are consistent with disc degeneration, there are no findings pathognomonic for DDD. As in any degenerative condition of the spine, begin the evaluation with a complete history and physical exam. Pursue atypical pain and other red flags vigorously. Then, assuming limited findings on physical exam, commence further management with a rigorous nonoperative management regimen.

Only patients failing this management after a 2-month trial require plain radiographic evaluation. While the changes on plain radiographs associated with disc degeneration do not necessarily confer a diagnosis, use plain radiography to exclude other potentially serious causes of pain. If these radiographs are negative, obtain flexion–extension lateral radiographs to rule out subtle instability.

In all cases, pay careful attention to psychosocial factors. A long period of evaluation and nonoperative management affords the surgeon an opportunity to get to know the patient well. Obtain an MMPI if there are any doubts as to the psychological profile. A motivated, professionally satisfied patient is the ideal candidate for further evaluation and possible surgical treatment.

The MRI is the study of choice in the evaluating the intervertebral disc. In the context of unresponsive mechanical pain in a psychologically normal individual,

On this inventory, somatic fixation tends to be predictive of poor surgical outcomes (68). Patients with low hypochondriasis and hysteria scores had 90% good to excellent results 1 year after surgery, while patients with higher scores had only a 10% rate of good to excellent results (69). Southwick and White (71) reported that patients in the latter category were more likely to have positive discograms at nondegenerated levels.

**SUMMARY OF THE ASSESSMENT STRATEGY**

While certain radiologic findings are consistent with disc degeneration, there are no findings pathognomonic for DDD. As in any degenerative condition of the spine, begin the evaluation with a complete history and physical exam. Pursue atypical pain and other red flags vigorously. Then, assuming limited findings on physical exam, commence further management with a rigorous nonoperative management regimen.

Only patients failing this management after a 2-month trial require plain radiographic evaluation. While the changes on plain radiographs associated with disc degeneration do not necessarily confer a diagnosis, use plain radiography to exclude other potentially serious causes of pain. If these radiographs are negative, obtain flexion–extension lateral radiographs to rule out subtle instability.

In all cases, pay careful attention to psychosocial factors. A long period of evaluation and nonoperative management affords the surgeon an opportunity to get to know the patient well. Obtain an MMPI if there are any doubts as to the psychological profile. A motivated, professionally satisfied patient is the ideal candidate for further evaluation and possible surgical treatment.

The MRI is the study of choice in the evaluating the intervertebral disc. In the context of unresponsive mechanical pain in a psychologically normal individual,
single-level degenerative changes may warrant consideration of operative treatment. Perform multilevel discography if several levels are involved or MRI findings are equivocal. Consider surgery only for those patients demonstrating one (possibly two) levels of concordant pain with no pain at control levels. Discography is at present not indicated in patients with a normal MRI.

NONOPERATIVE TREATMENT

Treat the vast majority of patients with mechanical LBP nonoperatively (4). Begin treatment at the initial patient encounter and, should the pain fail to improve, continue it through the protracted evaluation period. During this period, optimize the patient’s physiologic status through cessation of smoking, increasing spinal flexibility, and increasing aerobic exercise tolerance. Consider only patients actively participating in a surgeon-directed rehabilitation program for invasive presurgical testing, such as discography.

Specifically, institute a focused program of physical therapy including strengthening and stretching. Some have found that flexion exercises exacerbate discogenic pain. Specific abdominal strengthening and trunk-stabilizing exercises, such as abdominal crunches with flexed hips and knees, however, can be performed with limited lumbar flexion. Extension exercises and low-impact aerobic exercises, such as swimming and cycling, are often recommended and well tolerated.

For patients whose pain prevents them from being able to begin conditioning and strengthening exercises, start a course of acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs). Muscle relaxants may be useful in the setting of acute LBP but are not recommended for patients with chronic difficulties (5).

Chiropractic care may also have a role in the management of acute LBP episodes, although no convincing evidence of efficacy in the context of chronic LBP is available. Further, as in acute back pain, extended periods of bed rest have no role in the management of DDD patients. Several clinical trials have studied the role of bracing. The Quebec Task Force on Spinal Disorders found insufficient scientific evidence to support the efficacy of a lumbar corset or support (6, 14, 69).

Other nonoperative modalities such as traction, massage, and acupuncture for chronic, mechanical LBP are not supported by the scientific literature (89).

Consider a multidisciplinary pain clinic for patients who fail to adequately participate in a nonoperative regimen. In such a setting, detoxification, psychological assessment, work hardening, work skills retraining, tricyclic antidepressant medication, and other modalities may be effectively applied to improve the patient’s pain and functional status.

OPERATIVE TREATMENT

In general, offer surgery only to those patients for whom operative results would represent an improvement over the natural history of DDD. Since the natural history of DDD remains to be elucidated, balance any recommendations for surgery carefully against surgical risks and the significant possibility of failure to obtain clinical improvement.

Presently, 50% to 80% clinical success rates are reported for the various operative modalities in DDD. There are no data to suggest that the various subtypes of DDD require different approaches to surgical management.

Different outcomes measures have been used in the past to quantify acceptable surgical results. Often, failures result from unrealistic expectations on the part of both physician and patient. One factor is “fusion disease,” described by Zdeblick (69). The stripping and retraction required for posterior spinal fusion procedures may cause permanent fibrosis and ischemic injury of the extensor musculature. Long periods of intense manual labor may be impossible even in the presence of a solid bony union.

While fusions for multiple-level DDD typically fail, single-level (and occasionally double-level) fusions for DDD may be considered if the following prerequisites have been met (36):

- Pain and disability are present for at least 1 year.
- There is failure of aggressive physical conditioning and conservative treatment of more than 4 months duration.
- There is single-level disc degeneration on MRI with concordant pain response on discography.
- There is absence of psychiatric or secondary gain issues.

The aim of surgery for DDD is to decrease pain by limiting mechanical stimuli across the painful motion segment. The least controversial procedures achieve this goal by solid arthrodesis. Several methods currently advocated to promote such a fusion will be described next.

POSTEROLATERAL SPINAL FUSION

Posterolateral spinal fusion was previously the gold standard for the surgical treatment of discogenic back pain (36, 62). The advantage of the posterior approach is that fusion can be performed in the absence of the posterior element; the risk of injury to the neural elements is low, and because the graft is placed away from midline, there is less risk of iatrogenic spinal stenosis.

Reported results of uninstrumented fusion have been contradictory. Stauffer and Coventry (73) reported 89% good results, and they achieved an 80% fusion rate by radiographic criteria; there was a high correlation between successful fusion and the clinical result. Dawson et al. (11) reported a 92% rate of solid fusion, with a 70% to 90% clinical success rate. Those undergoing a fusion above the lumbosacral motion segment were found to have a 45% pseudarthrosis rate, however.

Others have noted poor results with fusion. Finlayson et al. (18) performed a posterolateral fusion for DDD in 20 patients with concordant discography. While 11 felt the operation was worthwhile, only six had a good outcome as measured by impairment, disability, and work status. Parker et al. (62) reported a prospective, consecutive series of patients with discogenic LBP undergoing posterolateral fusion. They observed only 35% good to excellent results, with 13% fair and 48% poor results. Poor results were associated with workers’ compensation status, pseudarthrosis, and being out of work longer than 3 months Greenough et al. (26) concluded that posterolateral fusion was an acceptable treatment for discogenic back pain only in very carefully selected patients.

Pedicle screw instrumentation has been added to posterolateral fusion procedures in an attempt to decrease pseudarthrosis rates (Fig. 145.13, Fig. 145.14). Data from fusion procedures for degenerative spondylolisthesis suggest increased fusion rates but no effect on clinical outcome (19). Instrumentation is associated with higher costs and complication rates. One recent series noted 10% of patients had instrumentation-related problems. Yet, biomechanical studies suggest that pedicle screw constructs are superior in stabilizing the nonosteoporotic spine (31). These constructs may confer immediate stability to motion segments and allow an expedited postoperative recovery. This added stiffness and faster recovery interval may be more important in the younger population with DDD than in the older patient with degenerative spondylolisthesis.

Figure 145.14. Postoperative lateral radiograph depicting fusion with instrumentation at L3-4.
Pseudarthrosis rates in noninstrumented fusions range from 35% to 68%. Instrumented fusions have pseudarthrosis rates reported from 0% to 33%. Increased rates of 75% to 95% significant clinical improvement are also reported in patients undergoing instrumented fusions, versus 59% to 70% in those fused without instrumentation (3,88). In patients undergoing fusion for discogenic pain, solid fusion is associated with increased return-to-work rates as well (11). Posterior lateral fusions undertaken to treat DDD should probably be undertaken with rigid, transpedicular instrumentation, particularly in the revision situation (85).

ANTERIOR LUMBAR INTERBODY FUSION

There are two common approaches to anterior lumbar interbody fusion (ALIF). The first, the open retroperitoneal approach, employs a 5–10 cm incision to directly access the anterior spine. A complete discectomy may then be undertaken and a variety of implants, including allograft rings and threaded cages, placed into the disc space. Various endoscopic methods of threaded cage placement have been described as well. These approaches use relatively straightforward techniques for access, but they do not include a complete discectomy. Moreover, the threaded cage techniques require violation of the vertebral endplate. While these newer approaches may be less invasive, long-term data regarding fusion rates and implant stability are not available.

Historically, ALIF has been reserved as a salvage procedure for patients failing multiple posterior procedures (27). More recently, increased ease of access and concerns over extensor muscle retraction in a relatively young patient population have renewed interest in this approach. Moreover, some authors, citing the disc as the primary source of pain, recommend its complete extirpation (27,29,43,56,72,82,89-90).

The advantages of ALIF include the following:

- Complete excision of disc material
- Placement of the graft under compression
- Availability of a large surface area for graft incorporation
- Availability of a virgin operative site if there has been a prior posterior spinal fusion
- Avoidance of extensor muscle injury (“fusion disease”)

Advocates of ALIF report that even after solid posterior arthrodesis, flexion may occur through the fusion mass. This slight movement may cause continuing pain in the intervening degenerated discs. Weatherly et al. (81) reported complete relief of pain after ALIF in four patients with solid posterolateral fusion and concordant discograms at the previously fused level. Because ALIF places the fusion mass at the center of motion of the spine, it more rigidly immobilizes the spine once it is solid (31,96).

Results of ALIF have included highly variable fusion rates from 18% to 96% (28). However, the pseudarthrosis rate is generally felt to be lower than that for one-level posterolateral fusions or posterior lumbar interbody fusions (70,88). Similar variability in rates of pain relief and return to work have been reported. Ostensibly, this variability is caused by differences in surgical indications and techniques.

Several distinct operative techniques have been described for ALIF (see Chapter 146). Traditionally, corticocancellous bone from the iliac crest was placed in the disc space and maintained in position with a screw and washer. This approach was sometimes associated with graft collapse and pseudarthrosis. Allograft rings were then recommended and, subsequently, threaded cage techniques.

The cited advantages of threaded cages include structural support for the anterior column, indirect decompression of the foramina and nerve roots by distraction of the disc space, the potential for bony ingrowth through the cage, and the possibility of minimally invasive implantation (90). While clinical results are preliminary, early series demonstrate good mechanical stability with these constructs (32). Figure 145.15 shows sample cases.

When considering the more recently described endoscopic methods of ALIF, it is important to remember that they represent only a new technique, not a new operation. Therefore, operative indications remain the same. There are proposed benefits of an endoscopic approach, however. Preliminary studies suggest shorter hospital stays, decreased morbidity, and earlier return to work with minimally invasive techniques (82,83).

At present, several endoscopic techniques are evolving. The transperitoneal approach with gas insufflation serves as a direct extension of conventional laparoscopic surgery (80). This technique allows direct access to L5–S1, L4–L5, and occasionally L3–L4. Proposed advantages include ease of organ retraction, more rapid exposure of the spine, increased working space, and decreased bleeding. Disadvantages include the requirement for expensive trocars with diaphragms and other special instruments, as well as the potential for air leakage and a carbon dioxide venous embolism.

A gasless approach has been devised wherein the working space is maintained by lifting the anterior abdominal wall with a fan-like retractor. This approach allows the use of conventional instruments and avoids carbon dioxide effects and expensive valves. The procedure is associated with increased time for exposure, limited lateral vision, and an overall more technically difficult approach. Therefore, an intermediate, combined insufflated and gasless technique was devised, in which insufflation is used for the initial spine exposure. Refractors and Steinmann pins are placed, and then conversion to gasless technique is undertaken.
For a retroperitoneal approach utilizing the potential space between the spine and the abdominal cavity, make a 2.5 cm flank incision by splitting the anterior lateral abdominal muscles. After an initial finger dissection, enlarge the space with a retroperitoneal balloon. Again, the laparoscopic retractor with a hydraulic arm is employed to create a tent-like effect. Further peritoneal reflection can then be carried out under direct vision. This procedure provides access from T-12 to S-1. Further, conventional instruments may be used and the procedure can be converted from a pure percutaneous endoscopic to an endoscopic-assisted anterior approach should the degree of difficulty be increased. Some authors report difficulty obtaining a direct frontal approach to the disc space with this technique, however.

GLOBAL FUSIONS

Global (360°) fusions were previously recommended for multilevel involvement and postlaminectionomy patients. Kozack and O’Brien (44) reported a series of 69 patients with global fusions for DDD. Fusion levels were determined by provocative discograms. With one- and two-level procedures, 90% fusion rates were achieved. Three- and greater procedures were associated with 77% fusion rates. Overall, 80% had acceptable clinical results. O’Brien et al. (59) described a global fusion procedure for 150 patients with severe disability due to back pain or with previous failed operations. With posterior instrumentation, they noted an 86% success rate.

Lower pseudarthrosis rates, usually 5% to 10%, were the principal justification for the added surgical morbidity of these combined procedures (44,76). More recently, concerns regarding the effectiveness of threaded cages as stand-alone devices has intensified the debate over the need for posterior stabilization.

A variation on this theme involves an endoscopic anterior fusion with a percutaneous posterior stabilization procedure with pedicle screws or translaminar facet screws, but there are no reports of long-term results.

POSTERIOR LUMBAR INTERBODY FUSION

A method of achieving an anterior arthrodhesis with posterior stabilization in a single surgical approach is the posterior lumbar interbody fusion (PLIF). A wide posterior decompression is performed, allowing retraction of the dural sleeve and nerve roots for complete disc excision and anterior column fusion.

The PLIF was introduced by Cloward in 1945 to treat lumbar disc ruptures (9). He stated that PLIF was indicated for “the treatment of low back pain with or without sciatica due to lumbar disc disease.” This procedure has also been recommended for spondylolisthesis, lumbar scoliosis, osteoemyelitis, lumbar kyphosis, and to increase posterior fusion rates in high-risk patients (e.g., smokers and diabetics).

In each case, the addition of an anterior load-sharing graft may enhance the fusion rate, stabilize the construct, and protect the posterior spinal implant by load sharing. In patients with deformity, the PLIF may aid in correction by partial anterior release. Most commonly, however, PLIF procedures are performed for discogenic back pain.

Cloward (9) summarized the PLIF as able to address “all sources of pathologic change of the motion segment in one operation, through one incision.” Yet, after initial enthusiasm, use of the PLIF declined due to high rates of pseudarthrosis and graft dislodgement. More recently, the advent of transpedicular instrumentation led to a resurgence of interest in PLIF. Steffee and Sitkowski (74) reported 104 fusions performed without graft dislocation, pseudarthrosis, or infection.

Reported advantages of PLIF include near total disc excision, restoration of disc height and normal sagittal contour, root decompression, solid mechanical arthrodesis, immediate load-sharing with structural support, large surface area for fusion between the vertebral endplates, fusion under compression, and avoidance of an additional anterior approach.

Disadvantages include graft displacement, pseudarthrosis, anterior and posterior destabilization, increased bleeding, dural tears, risk to nerve roots, and risk of epidural fibrosis from root retraction (38).

Ma (50) reported 100 consecutive PLIFs for back or leg pain, spondylolysis, or failed back syndrome. There was an 11% reoperation rate: six for pseudarthrosis, three for bone graft extrusion, one bone graft fracture, and one hematoma. Others have reported good to excellent results in 89%, with a fusion rates of 73% to 95% and an 82% return-to-work rate (49,76).

Of particular concern is the trauma to the nerve roots from wide retraction. Epidural fibrosis may develop into a chronic radiculopathy for which there is presently no satisfactory solution. Harms et al. (33) recently popularized a variant of the PLIF procedure that avoids significant retraction on the thecal sac. This posterior-lateral approach to the disc space relies on facet excision and has been termed the transforaminal lumbar interbody fusion (TLIF). While transpedicular instrumentation is recommended for the midline laminotomy version of the PLIF, it is mandatory here.

Transforminal lumbar interbody fusion preserves the anterior and posterior ligamentous complex, thereby maintaining a tension band for compression of the graft and prevention of retroprolapsed. While long-term outcome reports are not yet available, some authors noted the proximity of the dorsal root ganglion and the potential for chronic, neurogenic pain after even minor trauma to this structure.

Posterior lumbar interbody fusion is contraindicated in patients with preexisting, significant epidural fibrosis and those with significant osteopenia. Aside from the more typical complications such as bleeding, infection, and pseudarthrosis (mentioned later), the unique complications possible with PLIF deserve special mention here. With standard PLIF procedures, damage to nerve roots remains a principal concern. The surgeon must be careful about overdistraction, particularly in patients with nerve root anomalies. New or increased deficits occur in 0.5% to 4% of patients after PLIF (49). The upper (exiting) root traverses the interspace just out of direct view in the lateral recess and can be damaged when grafts are inserted in the disc space.

Steffee and Sitkowski (74) report that a failed PLIF has “a worse outcome than failure of any other fusion procedure.” They report that exploration of patients with a “fusion disease” chronic radiculopathy reveals epidural fibrosis for which there is no satisfactory salvage. Careful attention to the tension placed on the cauda and nerve roots may diminish the incidence of these problems.

Neural structures may also be injured with posterior bone graft migration. The subtotal discectomy required for a PLIF procedure risks penetration of the anterior annulus with attendant anterior vessel damage, a potentially catastrophic complication.

Revision options in failed PLIF are limited. A noninstrumented PLIF may be converted to an instrumented PLIF. A failed instrumented PLIF is most often revised with an attempted anterior fusion (80).

With the rising popularity of anterior approaches in the treatment of lumbar disc disease, the role of PLIF or TLIF is not entirely clear. For example, the importance of attempted anterior fusion (81,130).

Reported advantages of PLIF include near total disc excision, restoration of disc height and normal sagittal contour, root decompression, solid mechanical arthrodesis, immediate load-sharing with structural support, large surface area for fusion between the vertebral endplates, fusion under compression, and avoidance of an additional anterior approach.

Disadvantages include graft displacement, pseudarthrosis, anterior and posterior destabilization, increased bleeding, dural tears, risk to nerve roots, and risk of epidural fibrosis from root retraction (38).

Ma (50) reported 100 consecutive PLIFs for back or leg pain, spondylolysis, or failed back syndrome. There was an 11% reoperation rate: six for pseudarthrosis, three for bone graft extrusion, one bone graft fracture, and one hematoma. Others have reported good to excellent results in 89%, with a fusion rates of 73% to 95% and an 82% return-to-work rate (49,76).

Of particular concern is the trauma to the nerve roots from wide retraction. Epidural fibrosis may develop into a chronic radiculopathy for which there is presently no satisfactory solution. Harms et al. (33) recently popularized a variant of the PLIF procedure that avoids significant retraction on the thecal sac. This posterolateral approach to the disc space relies on facet excision and has been termed the transforaminal lumbar interbody fusion (TLIF). While transpedicular instrumentation is recommended for the midline laminotomy version of the PLIF, it is mandatory here.

Transforminal lumbar interbody fusion preserves the anterior and posterior ligamentous complex, thereby maintaining a tension band for compression of the graft and prevention of retroprolapsed. While long-term outcome reports are not yet available, some authors noted the proximity of the dorsal root ganglion and the potential for chronic, neurogenic pain after even minor trauma to this structure.

Posterior lumbar interbody fusion is contraindicated in patients with preexisting, significant epidural fibrosis and those with significant osteopenia. Aside from the more typical complications such as bleeding, infection, and pseudarthrosis (mentioned later), the unique complications possible with PLIF deserve special mention here. With standard PLIF procedures, damage to nerve roots remains a principal concern. The surgeon must be careful about overdistraction, particularly in patients with nerve root anomalies. New or increased deficits occur in 0.5% to 4% of patients after PLIF (49). The upper (exiting) root traverses the interspace just out of direct view in the lateral recess and can be damaged when grafts are inserted in the disc space.

Steffee and Sitkowski (74) report that a failed PLIF has “a worse outcome than failure of any other fusion procedure.” They report that exploration of patients with a “fusion disease” chronic radiculopathy reveals epidural fibrosis for which there is no satisfactory salvage. Careful attention to the tension placed on the cauda and nerve roots may diminish the incidence of these problems.

Neural structures may also be injured with posterior bone graft migration. The subtotal discectomy required for a PLIF procedure risks penetration of the anterior annulus with attendant anterior vessel damage, a potentially catastrophic complication.

Revision options in failed PLIF are limited. A noninstrumented PLIF may be converted to an instrumented PLIF. A failed instrumented PLIF is most often revised with an attempted anterior fusion (80).

With the rising popularity of anterior approaches in the treatment of lumbar disc disease, the role of PLIF or TLIF is not entirely clear. For example, the importance of “fusion disease” in these relatively young patients remains to be established (42). Certain criteria, however, may reasonably aid in the selection between ALIF and PLIF (Table 145.9).

Table 145.9. Soft Selection Criteria to Decide Between ALIF and PLIF
Because PLIF is a relatively difficult surgery to revise, present recommendations for PLIF include lumbar disc disease with sciatica (10) and certain revision situations in which an anterior/posterior fusion through a single incision is desirable.

SUMMARY OF TREATMENT OPTIONS

We feel that a posterior fusion with instrumentation is the gold standard for the rare patient with true lumbar segmental instability. Those patients with painful lumbar spondylosis LS are best served with a disc ablative procedure such as ALIF and PLIF. Circumferential fusions should be reserved for patients with significant canal pathologies, where revision is required, and other situations in which additional stabilization is required.

We favor ALIF because of the destabilizing effects of PLIF and its potential for nerve root injury, epidural fibrosis, and “fusion disease.” The advent of transfornaminal interbody fusion procedures may decrease the risk of the PLIF technique, but firm evidence is not available. As more information regarding the long-term results of interbody cage placement becomes available, treatment recommendations will no doubt be revised.

SURGICAL TECHNIQUES

Two surgical procedures commonly employed to treat DDD in its various forms are discussed here: posterior lumbar fusion (with and without instrumentation) and PLIF. ALIFs, either through traditional open or laparoscopic techniques, are increasingly favored for patients with these disorders and are covered in Chapter 146.

POSTEROLATERAL SPINAL FUSION

Before undertaking a posterior spinal fusion for DDD, carefully review your patient selection criteria. Be sure the patient is well informed as to the risks and the potential for an unsatisfactory clinical outcome. Pay careful attention to patient physiology by the following measures:

- Discontinue aspirin and NSAIDs.
- Ensure a good nutritional status.
- Have the patient stop smoking and other tobacco use.
- Recommend preoperative blood donation and institute prophylactic antibiotics.

A posterolateral fusion begins with proper patient positioning. Choose a frame or bolsters that allow the abdominal contents to be free of compression and maintain proper lumbar lordosis (Fig. 145.16).

Figure 145.16. Proper positioning on a frame that decompresses the abdomen and avoids pressure points is critical to the success of any lumbar fusion procedure.

- Freedom of abdominal contents will decrease epidural venous engorgement and blood loss.
- A Foley catheter similarly decreases intra-abdominal pressure by preventing bladder distention.
- Carefully pad all bony prominences and avoid pressure over the eyes.
- Use a radiolucent turning frame in procedures in which multiplanar image intensification is anticipated.
- Maintain the patient’s core body temperature with ventral and lower-extremity air-circulating devices.

As in all spine surgery, a headlight and loupes increase the effectiveness of the exposure. Intraoperative neural monitoring may be used to stimulate pedicle screws during placement to detect pedicular penetration.

Spine fusion procedures may be associated with significant blood loss. Intraoperative blood salvage is occasionally useful. More important, anticipate and control bleeder sites as you encounter them. Three fairly constant bleeding points include the pars interarticularis artery, the artery of Macnab (transverse process artery), and the sacral arteries.

- The pars artery is encountered during the initial exposure. Emerging from a recess inferior to the facet, it wraps around the pars.
- A curved bayonet may help control the artery of Macnab, which lies on the upper aspect of the junction of the transverse process.
- The sacral arteries protrude from the posterior sacral foramina and are difficult to control without inserting bipolar cautery or forceps into the bony recess. Often, temporary packing with Gelfoam will provide adequate hemostasis.
- Begin the exposure by centering a 6–10 cm midline skin incision just cranial to the involved level (Fig. 145.17).

Figure 145.17. Initiation of a midline subperiosteal approach.

- Inject a dilute epinephrine solution into the skin and subcutaneous tissue to decrease bleeding.
- Use electrocautery to proceed through the subcutaneous tissue to the fascia.
- Expose a 0.5 cm portion of the fascia on either side of the midline to aid subsequent closure. Avoid extensive fascial stripping, which increases dead space.
- Enter the deep space over the spinous processes in a subperiosteal fashion. Use the Cobb elevator for countertraction.
- Carry the subperiosteal dissection over the laminae to the facets with the electrocautery. Do not violate the facet capsules at this point.
- Insert a Penfield #4 elevator (Fig. 145.18) under a lamina and obtain a radiograph. Confirm operative levels and mark the superior level by resecting a portion of the spinous process with a rongeur.
Expose the laminae one level above and one level below the anticipated level of fusion. Leave the facets intact at these levels. This additional dissection will reduce tension over the transverse process exposure at the operative level.

Bluntly dissect over the facets with a Cobb elevator and a sponge at the operative level.

Then expose the lateral pars interarticularis and transverse processes with electrocautery. The transverse processes lie immediately adjacent to the facets. Be careful not to penetrate the intertransverse membrane (Fig. 145.19).

If no midline decompression is required, consider a bilateral Wiltse (paramedian) approach. A larger midline skin incision and subcutaneous dissection is required. Make the fascial incisions two finger breadths lateral to the midline bilaterally. Then bluntly dissect down to the lateral facets between the multifidus and longissimus muscles. This approach is covered more extensively in Chapter 138.

Remove all soft tissue from the posterior aspect of the transverse processes, outer facets, and pars. If the fusion includes S-1, clear the sacral ala. Complete soft-tissue removal will double the area available for bone graft. Preparation of the graft bed is the most important part of any fusion procedure.

Decorticate the lateral pars, the transverse process, and the lateral wall of the facets.

Lay autologous cancellous bone into place and impact gently. Then add corticocancellous strips and compress gently into position.

For each level to be included in the fusion, remove the entire facet joint capsule and denude the cartilage from the facet.

Close the wound in layers to create a watertight fascial closure. Place a drain in the deep space.

HINTS AND TRICKS

To diminish operative morbidity in posterior approaches, do the following:

- Periodically release the retractor to reestablish muscle vascularity.
- Handle muscle carefully to minimize devascularization and necrosis.
- Make the exposure generous to minimize the required retractor tension.
- Use Gelfoam or bipolar cautery over the pars, transverse processes, neural foramen, and dorsal sacral foramen.
- Prevent overcauteration to minimize injury to nearby neural structures.

INSTRUMENTED POSTERIOR SPINAL FUSION

Employ the same initial steps as in a noninstrumented fusion. Do not insert pedicle screws prior to complete exposure of the posterior elements. Decortication of the transverse processes and bone graft insertion are more easily and completely accomplished prior to hardware insertion. Many surgeons, however, prefer to decorticate after instrumentation to diminish blood loss.

Several useful techniques for entry-point localization and pedicle-screw placement have been described. Thorough knowledge of pedicle anatomy is critical. Various radiographic techniques of localization are now available, but none replaces a firm grasp of the relationships of the posterior elements to one another.

The pedicle lies along the midline axis of the transverse process. The outer border of the facets describes a line roughly conforming to the lateral border of the pedicle. The lateral border of the pars defines the medial pedicular border. The accessory process is often identified at the junction of the facet and the transverse process. This process serves as a useful entry point (Fig. 145.20A).

While multilevel fusions are generally not recommended for DDD, instrumentation in these cases is placed at each level in an effort to reduce micromotion. How much segmental stiffness is required to achieve fusion and eliminate pain is not established (45); however, given that micromotion has been hypothesized as a cause of pain in four screw micromotion-segment constructs (81), maximizing points of fixation is recommended. Screw placement is abandoned if preoperative imaging demonstrates thin pedicles. Similarly, if difficulties with cortical breach are noted intraoperatively, abandonment of that point of fixation is recommended.

Carefully review the preoperative MRI or CT scan to confirm the extent of convergence of the pedicle at each level, as well as the length and size of screw...
In general, screws should converge by 5° at the thoracolumbar junction. This convergence increases to 10° at L-2 and 15° at L-5.

Use the localization lateral radiograph to define the proper aperture of the pedicle in the cranial and caudal planes.

Most often, an L-3 pedicle screw is inserted perpendicular to the floor. Angle superior screws progressively more cranially. Angle inferior screws progressively more caudally.

Decorticate the pedicle entry site with a burr.

Enter the pedicle with a curet or pedicle probe. Gently work this device anteriorly into the vertebral body (Fig. 145.20B).

Check for cortical penetration with a ball-tip probe. If a midline decompression has been performed, the pedicle may also be palpated from within the canal. If necessary, place markers and confirm radiographically.

Tap the hole and insert the screw (Fig. 145.20B). The optimal depth of screw placement has not been determined, but pullout strength increases linearly with depth of penetration (46). We estimate 75% penetration using lateral fluoroscopy to increase purchase while minimizing risk to anterior vascular structures.

Once the screws and bone graft have been placed, affix a plate or rod according to the manufacturer’s instructions.

Be careful to maintain proper lumbar lordosis.

Undertake closure over a drain with watertight fascial closure, and follow with a layered closure of the subcutaneous tissues and skin.

SACRAL FIXATION

Sacral fixation remains the weak link in posterior fixation systems (13). Large constructs extending to the sacrum require additional fixation. The combination of large forces transmitted to the sacrum and the size and bone content of the sacral pedicle may render S-1 screws inadequate as the sole point of inferior fixation. In the degenerative conditions described in this chapter, however, smaller, single-level constructs are recommended. In these cases, simple transpedicular instrumentation is usually successful. The sacral pedicle requires larger screws.

Locate the S-1 pedicle at the intersection of a horizontal line connecting the inferior aspect of the lumbosacral facets, and a vertical line tangential to the lateral border of the superior facet.

Insert the screws above and in line with the first sacral foramen. Converge the screws and incline them superiority, parallel with the lumbosacral disc space.

Medial angulation allows longer screws with superior fixation strength, although iliac crest overhang may limit optimal screw trajectory. In the case of tenuous fixation, additional cortical purchase is recommended to prevent “windshield-wiping.” Options include careful perforation of the anterior cortex or of the L5–S1 disc space (Fig. 145.21).

When considering penetration of the anterior sacral cortex, recognize the possibility of significant individual anatomic variability (13). Differences in sacral bony anatomy are associated with differences in vascular tree branching patterns and in the location of the neural foramina. Assess the morphology and choose an optimal trajectory from preoperative CT or MRI scans.

The medial sacral promontory is the safest place to penetrate the anterior cortex. More lateral sacral screws may hit the lumbosacral plexus, which is affixed to the bone here. Lateral trajectories also risk injury to the iliac veins, particularly on the left.

Other options for fixation below the lumbosacral interspace include S-2 pedicle screws, sacroiliac bolts, and sacral rods. S-2 screws are easily inserted along the intermediate sacral crest midway between the first and second dorsal foramina, but they are considered biomechanically weak. Cortical penetration at this level risks injury to the sigmoid colon.

Postoperative bracing is not usually recommended, and genuinely effective bracing requires a pantaloon extension. Sacral fixation techniques are further discussed in Chapter 156, Chapter 159 and Chapter 160.

POSTERIOR LUMBAR INTERBODY FUSION

Carry out the initial stages of PLIF (13,48,74) in the same manner as posterolateral fusion. Careful positioning is critical. Lumbar lordosis and abdominal decompression are important. Some authors feel the knee–chest position adequately maintains lordosis while maximizing hip and knee flexion. Hip and knee flexion ensure decreased tension on the nerve roots, which may allow greater thecal sac retraction for PLIF surgery.

Although PLIF was originally described without instrumentation, this is not recommended. The wide posterior exposure necessary for a safe PLIF produces increased instability with increased rates of pseudarthrosis and graft dislodgement.

Classically, a PLIF is performed in three steps: laminotomy, removal of the intervertebral disc, and spinal fusion.

Perform a standard 10 cm midline exposure of the posterior elements (as described previously) with a wide laminotomy at the level of interest.

Preserve the superior portion of the superior lamina and the inferior portion of the inferior lamina with portions of the spinous processes. Muscular attachment sites and interspinous ligaments to levels above and below operative level are thereby preserved.

Remove the inferior third of the inferior facet, and the medial two thirds of the superior facet to the level of the pedicle. Visualize the lateral half of the intervertebral disc as well as the cranial and caudal nerve roots.

The medial facet resection can be more aggressive if a combined posterior fusion and instrumentation is planned (Fig. 145.22).

When considering penetration of the anterior sacral cortex, recognize the possibility of significant individual anatomic variability (13). Differences in sacral bony anatomy are associated with differences in vascular tree branching patterns and in the location of the neural foramina. Assess the morphology and choose an optimal trajectory from preoperative CT or MRI scans.

The medial sacral promontory is the safest place to penetrate the anterior cortex. More lateral sacral screws may hit the lumbosacral plexus, which is affixed to the bone here. Lateral trajectories also risk injury to the iliac veins, particularly on the left.

Other options for fixation below the lumbosacral interspace include S-2 pedicle screws, sacroiliac bolts, and sacral rods. S-2 screws are easily inserted along the intermediate sacral crest midway between the first and second dorsal foramina, but they are considered biomechanically weak. Cortical penetration at this level risks injury to the sigmoid colon.

Postoperative bracing is not usually recommended, and genuinely effective bracing requires a pantaloon extension. Sacral fixation techniques are further discussed in Chapter 156, Chapter 159 and Chapter 160.

POSTERIOR LUMBAR INTERBODY FUSION

Carry out the initial stages of PLIF (13,48,74) in the same manner as posterolateral fusion. Careful positioning is critical. Lumbar lordosis and abdominal decompression are important. Some authors feel the knee–chest position adequately maintains lordosis while maximizing hip and knee flexion. Hip and knee flexion ensure decreased tension on the nerve roots, which may allow greater thecal sac retraction for PLIF surgery.

Although PLIF was originally described without instrumentation, this is not recommended. The wide posterior exposure necessary for a safe PLIF produces increased instability with increased rates of pseudarthrosis and graft dislodgement.

Classically, a PLIF is performed in three steps: laminotomy, removal of the intervertebral disc, and spinal fusion.

Perform a standard 10 cm midline exposure of the posterior elements (as described previously) with a wide laminotomy at the level of interest.

Preserve the superior portion of the superior lamina and the inferior portion of the inferior lamina with portions of the spinous processes. Muscular attachment sites and interspinous ligaments to levels above and below operative level are thereby preserved.

Remove the inferior third of the inferior facet, and the medial two thirds of the superior facet to the level of the pedicle. Visualize the lateral half of the intervertebral disc as well as the cranial and caudal nerve roots.

The medial facet resection can be more aggressive if a combined posterior fusion and instrumentation is planned (Fig. 145.22).
The TLIF variant (TRANSFORAMINAL LUMBAR INTERBODY FUSION) instrumentation warrants a heightened awareness of the position of and tension on the dura and nerve roots. Requires a larger laminotomy or complete laminectomy and facetectomy. Base implant sizing on preoperative templating. Furthermore, the larger size of the posterior insertion of threaded interbody cages. While the specific instruments vary by the system used, the concepts are the same. The larger size of these implants use of morcelized cancellous bone rather than corticocancellous pieces may minimize donor site morbidity. Specialized instrumentation has been developed for the Cages are designed to prevent postoperative collapse by providing a structural support to the interspace while the cancellous graft material becomes incorporated. The Figure 145.23. Bone grafting options in PLIF. A: Sagittal, axial, and posterior views (from top to bottom) of Cloward's (9) tricortical rectangular graft technique. B: Similar views of threaded bone dowels used to obtain a PLIF. Cages are designed to prevent postoperative collapse by providing a structural support to the interspace while the cancellous graft material becomes incorporated. The use of morcelized cancellous bone rather than corticocancellous pieces may minimize donor site morbidity. Specialized instrumentation has been developed for the posterior insertion of threaded interbody cages. While the specific instruments vary by the system used, the concepts are the same. The larger size of these implants requires a larger laminectomy or complete laminectomy and facetectomy. Base implant sizing on preoperative templating. Furthermore, the larger size of the instrumentation warrants a heightened awareness of the position of and tension on the dura and nerve roots. In some systems (e.g., the BAK), a drill tube is available to dock onto the disc space posteriorly. This allows insertion of the remainder of the instrumentation in a relatively safe fashion. The instrumentation includes distraction plugs or other devices to open the disc space, reamers to remove disc and endplate tissue, taps to prepare the threaded cage path, and cage inserters. When using this instrumentation, avoid long periods of traction on the dural sleeve with the tube in place. Insert remaining autograft around the cage in the disc space. If individual bone pieces are used, pack the anterior disc space first, then pack medially under the thecal sac, then laterally. In all cases, countersink the graft material 3–5 mm to prevent canal encroachment. Some authors recommend placing a fat graft anteriorly between the dura and the grafts. Once maximal fill of the disc space has been achieved, remove the distractive forces to allow compression of the graft. With transpedicular instrumentation, further compression is achieved across the screws before final tightening. In all cases, make sure that appropriate lordosis is maintained. TRANSFORAMINAL LUMBAR INTERBODY FUSION The TLIF variant (33) of the standard PLIF procedure requires a wide, unilateral approach to the disc space at its posterolateral aspect. First remove the inferior facet of the superior vertebra with an osteotome. Then remove the superior facet of the inferior vertebra (Fig. 145.24). Identify and protect the exiting and traversing nerve roots. After the pedicles have been identified, insert pedicle screws. Distract the disc space with an intervertebral spreader and maintain the distraction with working plates or rods affixed to the screws. Perform an annulotomy by creating a medially based annular flap. This flap may aid in thecal sac protection. Perform a complete discectomy, as described previously, and increase disc space distraction after the annulotomy. Insert additional graft into an oblong 10–12 mm Harms cage (Fig. 145.25). Tamp the cage across the disc space to the contralateral side with either a straight or an angled impactor.
Then, only after rigorous selection criteria are fulfilled, may a patient be considered for surgery. Lumbar fusion remains the treatment of choice. In any operative trial of nonoperative treatment is indicated. Should symptoms continue, a progressive preoperative evaluation including MRI and psychosocial assessment is Evaluation of DDD requires exclusion of other causes of pain. Begin investigation with a thorough history and physical examination. In the absence of red flags, a long subclassified with names such as internal disc disruption, lumbar segmental instability, and lumbar spondylosis. These distinctions are largely conjectural and almost syndrome has been fraught with failure. A range of painful degenerative lumbar conditions exists. These entities have been grouped as degenerative disc disease or changes ascribed to DDD, however, are similar to the changes of normal aging. Moreover, a clear understanding of the pathophysiology and natural history of this pain Recent studies demonstrate that the disc may be a source of back pain via nocireceptors and mechanoreceptors in the annulus and chemical irritants from the NP. The

**REHABILITATION AND POSTOPERATIVE PRINCIPLES**

Regardless of the approach, early mobility is a prime postoperative goal.

- Mobilize patients to a chair the evening after surgery. No braces are employed.
- Request physical therapy assistance for ambulation and transfer techniques in the early postoperative period. Most patients can comfortably ambulate by the third day after surgery. Typically, young DDD patients rarely require assistive devices.
- Early postoperative restrictions include limitations on bending, lifting, and twisting, but other gentle activities are encouraged.
- After posterior fusion, remove drains and Foley catheters on the first postoperative day.
- At present, we use 24–48 hours of postoperative antibiotics.

Most patients are ready for discharge by the third postoperative day. See them for a wound check and staple removal at 7–14 days after surgery. Subsequent visits include 6- and 12-week checks. Obtained radiographs at these intervals to assess the status of the fusion.

The schedule for return to work and sporting activities is individualized on the basis of clinical status, radiographic union, and the nature of the activities involved. Early return with limited duty is preferred to lengthy sick leave.

After solid fusion is achieved, aerobic activities, spinal flexibility, and truncal strength and stability are important, life-long aspects of the patient's personal fitness regime. Further specific physical therapy is not usually needed, however.

Some patients may not be able to return to physically demanding occupations. Early intervention with skills retraining and a realistic outlook are crucial to optimal functional recovery.

**PITFALLS AND COMPLICATIONS**

It is important to appreciate the scope and magnitude of potential pitfalls before selecting one of these procedures. Perisurgical problems include general surgical complications and specific procedure-related complications. The latter are detailed in their respective sections. Also, see [Chapter 147](#).

General complications can be divided temporally into preoperative, intraoperative, and postoperative problems. Preoperative problems include the following:

- Wrong patient. Patient selection cannot be overemphasized.
- Wrong level. Correct identification of a pain generator amenable to surgical treatment is fraught with difficulty and remains the biggest hurdle in the treatment of patients with disc degeneration.
- Wrong surgery. Fusion procedures, particularly disc ablative procedures, are the only acceptable surgical modalities for DDD patients.
- Wrong doctor. Anterior and posterior spinal fusion procedures are technically demanding and should be practiced only by surgeons with special training.

Intraoperative complications are often site specific. Anterior and posterior approaches have a unique complement of attendant problems.

Adjacent segment degeneration is a significant problem in young, active patients with stiff spinal segments. While risks and pathomechanics are not entirely understood, some patients will require extension of fusion in the future for painful degeneration above or below the index fusion.

The risks of pseudarthrosis relative to each procedure have been discussed. In general, grafts under compression have lower pseudarthrosis rates. But anterior column applications require structural graft or cage support. Autogenous structural grafts have higher structural morbidity. Allografts may have higher collapse potential. Further, autogenous bone harvest is recommended in each of these procedures. The morbidity of bone graft harvest, covered in [Chapter 9](#), should not be underestimated.

Failure to improve despite solid fusion is most often related to poor patient selection or misidentification of the pain generator. In some cases, a solid posterior fusion may allow painful micromotion of the painful disc anteriorly (as described in the section on [ALIF](#)).

Benign postoperative urinary retention is common, but cauda equina syndrome and other postsurgical causes must be excluded. Further, indwelling catheters or repeated instrumentation of the genitourinary tract may lead to urinary tract infection and subsequent sepsis.

Ileus may be seen after posterior spine surgery, but it is more common after transperitoneal approaches or those retroperitoneal approaches that violate the peritoneum.

Deep vein thrombosis and pulmonary embolism, while less common than after hip and knee procedures, have rates similar to those in most general surgery procedures. Use of intermittent pneumatic compression stockings after surgery is recommended as a mechanical prophylaxis against this potentially fatal complication.

**AUTHORS' PERSPECTIVE**

Recent studies demonstrate that the disc may be a source of back pain via nocireceptors and mechanoreceptors in the annulus and chemical irritants from the NP. The changes ascribed to DDD, however, are similar to the changes of normal aging. Moreover, a clear understanding of the pathophysiology and natural history of this pain complex is lacking. Given the ubiquity of back pain in society at large, isolating those symptom patterns and imaging findings consistent with a surgically treatable pain syndrome has been fraught with failure. A range of painful degenerative lumbar conditions exists. These entities have been grouped as degenerative disc disease or subclassified with names such as internal disc disruption, lumbar segmental instability, and lumbar spondylosis. These distinctions are largely conjectural and almost nothing is known about their natural histories.

Evaluation of DDD requires exclusion of other causes of pain. Begin investigation with a thorough history and physical examination. In the absence of red flags, a long trial of nonoperative treatment is indicated. Should symptoms continue, a progressive preoperative evaluation including MRI and psychosocial assessment is mandatory. Based on these studies, discography may be indicated to identify concordant pain at abnormal levels seen on MRI.

Then, only after rigorous selection criteria are fulfilled, may a patient be considered for surgery. Lumbar fusion remains the treatment of choice. In any operative
procedure, the known benefits must outweigh the risks. As the benefits of fusion for DDD have not been clearly established, a great deal of further study is required before routine operative intervention can be recommended for these patients.

In some circumstances, dual-level surgery may be justified. However, results of multilevel fusion for painful disc degeneration are abysmal, and it is best avoided. Multidisciplinary pain clinics remain a viable alternative.

Questions surrounding surgical approach are rapidly evolving. Presently, minimally invasive anterior approaches with threaded cages appear promising, but significant long-term data are lacking. PLIF techniques are also frequently employed. A transforaminal posterior interbody fusion may be a sensible approach in certain patients. As with any major posterior lumbar procedure, however, the long-term effects of "fusion disease" in an otherwise active patient population must be considered. With reasonable results reported for each of the various anterior and posterior procedures, the surgeon should ultimately choose which technique with which she is most comfortable. The most important factor in clinical success with this group of patients remains patient selection.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: * classic article; §, review article; !, basic research article; and +, clinical results/outcome study.

Perhaps no topic has generated as much interest in orthopaedic spine surgery over the past 10 years as anterior lumbar interbody fusion (ALIF). Although anterior fusions have been performed on the spine for more than 50 years, it is only recently that interest in the procedure has exploded. Traditionally, anterior or anterolateral approaches to the lumbar spine were performed for tumor, trauma, or infections. In these cases, debridement, strut grafting, and occasionally anterior fixation were used to decompress the spinal canal or stabilize the anterior spinal column. The advantages of these procedures included direct spinal canal decompression and reconstruction of the weight-bearing capability of the anterior column. Another advantage is that they avoid injury to posterior muscles.

The avoidance of posterior muscle dissection is important. Often, when posterolateral fusions were performed for degenerative disc problems, patients would have continued complaints of fatigue and weakness in the lumbar spine. Some of these symptoms may have been due to injury to the paraspinal muscles leading to "fusion disease" (19). In addition, over the past several decades, much research has pointed to the disc as a predominant source of chronic low back pain (see Chapter 144). Fusion procedures that eliminate discs entirely may offer advantages that more traditional posterior fusions do not. For both of these reasons, the indications for ALIF have greatly expanded over the last decade.

INDICATIONS
Lumbar interbody fusion is indicated in selected patients with degenerative disc disease, internal disc derangement, spondylolisthesis, pseudarthrosis, and, occasionally, scoliosis, trauma, or infection. Each case must be evaluated on an individual basis to determine the appropriateness of surgical intervention.

DEGENERATIVE DISC DISEASE
Degenerative disc disease shows radiographic changes of disc-space narrowing, endplate sclerosis, osteophyte formation, and occasionally vacuum phenomena within the disc space. Magnetic resonance imaging (MRI) corroborates this diagnosis, revealing "Modic" changes in the endplates surrounding the degenerative disc (14). Many of these changes can be traced to a previous episode of disc herniation that had been treated either with or without surgery. Often, in these cases, the sciatica has resolved but has been replaced by persistent chronic midline low-back pain.

Many patients with degenerative disc disease complain of pain over the sacroiliac joints, particularly if the L5–S1 disc space is involved. Most patients with degenerative disc disease can be successfully treated with an aggressive physical therapy program that includes trunk stabilization exercises and nonimpact aerobics. In the majority, symptoms improve, and patients decide to live with a low-level midline low-back ache. Other modalities that may be helpful include short-term periods of bracing, administration of nonsteroidal antiinflammatory medication, and occasionally manipulation. Epidural steroid injection, prolonged bed rest, transcutaneous electrical nerve stimulation units, and passive modalities such as heat, massage, or ice have not been proven to be of benefit.

Before offering surgery, evaluate a patient's psychological profile. Office findings of pain behaviors, Waddell's signs, chronic narcotic use, or excessive secondary gain are contraindications for surgical treatment (see Chapter 144). In addition, evaluate the adjacent discs. Ideally, only a one- or two-level fusion should be performed for degenerative disc disease. Fusion of more than two levels leads to less satisfactory clinical results. MRI of the adjacent discs is an excellent screening test. With normal MRI findings, it is safe to assume that the adjacent disc can be left untouched. If MRI is abnormal, then discography may be indicated to evaluate adjacent-levels for fusion.

INTERNAL DISC DERANGEMENT
Patients with a normal radiographic examination but abnormal MRI may have internal disc derangement (IDD). The MRI abnormalities of IDD include decreased signal intensity within the disc nucleus on T2-weighted images, annular tears (with or without enhancement), and high-intensity-zone lesions. In these cases, initiate a similar nonoperative treatment program before considering surgical therapy. Should patients satisfy diagnostic criteria and fail to improve with adequate conservative measures over 3–4 months, then discography is indicated for confirmation of the diagnosis. A positive discogram should include reproduction of the patient's symptoms upon injection, abnormal morphology with dye leakage through annular disruptions, and normal adjacent-level injections without pain reproduction (5). A patient who meets all of these criteria may be a candidate for ALIF surgery (1,6).

Other treatment modalities may include steroid injection within the disc, thermal repair of the disc annulus, or annular debridement. ALIF surgery, however, has the longest history of successful results in the treatment of this condition. It must always be kept in mind, however, that success is not universal in the treatment of patients with IDD. Many clinical reports document success rates in the 50% to 70% range (1,6,7,8 and 9). Patient selection is critical. Offer ALIF only to highly motivated patients with single-level disease who have no psychological overlay, secondary-gain issues, or chronic narcotic use. Only strict selection criteria will lead to an acceptable success rate from surgery.

SPONDYLOLISTHESIS
Often, degenerative spondylolisthesis with spinal stenosis does not require ALIF. Most patients with this condition can be successfully treated with posterior decompresion and posterolateral fusion techniques (19). In adult isthmic spondylolisthesis, however, ALIF plays an important role (see Chapter 162).

My approach to adult isthmic spondylolisthesis has evolved over the years. In patients in whom reduction of a spondylolisthesis is planned, anterior interbody support is necessary to prevent late hardware failure or pseudarthrosis. In patients with spondylolisthesis with a well preserved disc space and translational motion on flexion–extension films, anterior interbody support in addition to posterior fixation is necessary to achieve a high incidence of solid fusion. In patients with a collapsed disc space with degenerative changes, as well as isthmic spondylolisthesis, fusion with either anterior procedures alone or posterior procedures alone may be successful. Interbody fusion cages alone have successfully been used in this subset of spondylolisthesis patients. Exercise caution, however, when using cages alone for a spondylolisthesis patient who has a preserved disc space and hypermobility. In these cases, it is often difficult to obtain stability through the use of anterior cages alone.

DEFORMITY
In selected cases of scoliosis and kyphosis in which correction will be performed, anterior release and interbody fusion are indicated. In addition, for patients with
traumatic endplate disruption or disc space infection, debridement and interbody fusion are helpful. Finally, in cases of previous pseudarthrosis of a posterosuperior fusion, interbody fusion is often the only means of obtaining a solid arthrodesis. In addition, it avoids dissection through a previously scarred posterior paraspinal muscle approach.

**SURGICAL TECHNIQUES**

Anterior lumbar interbody fusion surgery can be performed through a variety of surgical approaches. Open approaches include the transperitoneal, anterior retroperitoneal, and retropertioneal flank approaches. For endoscopic techniques, the anterior transperitoneal laparoscopic approach has become popular, as has the retropertitoneal endoscopic approach using balloon insufflation or gasless techniques. All of these approaches require an excellent knowledge of the anatomy surrounding the middle and low lumbar spine (Fig. 146.1).

**OPEN TECHNIQUES**

**Open Transperitoneal Approach**

The open transperitoneal approach is the oldest and most traditional approach to the anterior lumbar spine.

- Make a midline vertical skin incision, and split the fascia between the rectus abdominis muscles (Fig. 146.2).
- Enter the peritoneal cavity, and retract the small bowel superiorly and the sigmoid colon to the left laterally.
- Typically, the aorta and vena cava bifurcate at the level of the L-5 vertebra. There is considerable variation, however, so check the preoperative MRI to confirm the level.
- To expose the L5–S1 disc space, incise the peritoneum vertically overlying the disc space. This incision can be safely made between the bifurcation of the vessels. Ligation and control of the middle sacral artery and vein is necessary for complete disc exposure. At L4–5, the most common access pathway is to the left of both of the great vessels, with retraction in a left-to-right direction. This requires control and ligature of the iliolumbar vein for complete vessel mobility. Use blunt dissection only at both levels to prevent damage to the presacral nerve plexus.
- Cut the peritoneum without cautery, and dissect over the disc space bluntly to minimize the risk of damage to the nerve plexus. In men, retrograde ejaculation may result if this plexus of nerves is damaged.
- Once it is ligated, adequate mobilization of the great vessels is usually obtained. If possible, avoid dissection between the aorta and vena cava.
- The presacral plexus nerves are particularly vulnerable during dissection between the great vessels.
- At L3–4 disc space, the aorta and vena cava are more mobile, although segmental vessels need to be ligated to obtain exposure.
- After exposure is obtained, it is mandatory that the vascular structures be protected throughout the fusion procedure. I prefer to drive four Steinmann pins covered with a red rubber catheter into the endplates above and below the disc space to be worked on. These four pins serve as self-retaining retractors, providing a safe zone in which to perform the fusion. Other retraction systems are available, as well as self-retaining blades that may be staked through the vertebral endplates.
- Take particular care to avoid injury to the vena cava and common iliac veins. Once exsanguinated by the retraction, they are difficult to visualize and are prone to injury.
Transperitoneal exposures of the lumbar spine above L-3 are difficult because of the renal and mesenteric vessels. At these levels, the flank retroperitoneal approach offers a lateral exposure of the lumbar vertebral bodies. This approach is most useful when debridement for infection, trauma, or tumor is required. When corpectomy is necessary, a lateral plate device is useful for stability and can best be placed from a lateral approach. If debridement and grafting alone are being performed, the anterolateral or anterior approach is adequate.

Flank Approach

The flank approach involves an oblique incision centered over the area of pathology of the lumbar spine. It parallels the twelfth rib and is anywhere from 4 to 8 in (10–20 cm) long, depending on the size of the patient.

- Use fluoroscopy to center this incision directly over the level of pathology.
- Should exposure of the low lumbar spine be required as well, curve the incision across the lateral aspect of the abdomen.
- After incising the skin, divide the external oblique, internal oblique, and transversalis muscle layers in line with the incision.
- Take care when dividing the transversalis to ensure that the reflection of the peritoneum is free.
- Once the transversalis fascia is divided, enter the retroperitoneal space, which is behind the fascia surrounding the kidney and thus is truly behind Girota's fascia.
- After entering the retroperitoneal space, identify the psoas muscle, and take care to preserve the ilioinguinal nerve lying on its surface.
- The origin of the psoas muscle is usually at the L-1 body, and each of the lumbar nerve roots as they exit the foramina run in the substance of the psoas muscle.
- For this reason, the psoas must be retracted in an anterior-to-posterior direction to expose the appropriate disc space.
- Perform this exposure, using elevators and cautery, controlling segmental vessel as needed.

This approach gives excellent visualization of the lateral aspect of the disc and vertebral body; it is limited posteriorly by the level of the nerve at the foramen and anteriorly by the great vessels. If necessary, dissect the anterior longitudinal ligament free from the vertebral bodies, and carry out subperiosteal dissection around to the opposite side of the vertebral body. This maneuver permits complete release of all soft-tissue structures in cases of deformity.

Anterior Rectus–sparing Retroperitoneal Approach

My preferred approach for ALIF is the anterior rectus-sparing retroperitoneal approach. In this approach, none of the muscles of the abdominal wall is divided, and therefore quick recovery is possible. I prefer a transverse incision.

- Begin in the midline, and extend the incision to the left for approximately 3–4 in (7.5–10 cm).
- Divide the anterior rectus sheath, and retract the rectus muscle from the midline to the left.
- Identify the posterior rectus sheath and the arcuate line.
- Use blunt dissection beneath the arcuate line to enter the preperitoneal space, and continue the dissection laterally to the left until you are lateral to the peritoneal contents and the psoas muscle can be identified.
- Place a retractor to pull the peritoneal contents toward the midline to expose the retroperitoneal space overlying the spine.
- Identify the left ureter, and protect it throughout the procedure. In general, in cases involving the L3-4 or L4-5 disc space, the ureter will be retracted toward the opposite side of the vertebral body.
- Place a retractor to pull the peritoneal contents toward the left for approximately 3–4 in (7.5–10 cm).
- Divide the anterior rectus sheath, and retract the rectus muscle from the midline to the left.
- Identify the posterior rectus sheath and the arcuate line.
- Use blunt dissection beneath the arcuate line to enter the preperitoneal space, and continue the dissection laterally to the left until you are lateral to the peritoneal contents and the psoas muscle can be identified.
- Place a retractor to pull the peritoneal contents toward the midline to expose the retroperitoneal space overlying the spine.
- Identify the left ureter, and protect it throughout the procedure. In general, in cases involving the L3-4 or L4-5 disc space, the ureter will be retracted toward the midline with the visceral peritoneum. At the L5-S1 space, the ureter will usually be on the left side of the incision and will be retracted laterally.
- Identify the sympathetic chain running on the psoas muscle and protect it.
- The dissection at this point proceeds in much the same fashion as previously described (see "Open Transperitoneal Approach" above).
- Bluntly dissect the tissues lateral to the aorta and vena cava at the L4–5 space or between the great vessels at L5–S1.
- At L5–S1, ligate the middle sacral artery and vein to allow blunt dissection to proceed along the annulus.
- Several self-retaining retraction systems are available for use through this "mini-laparotomy (minilap)" approach.

ENDOSCOPIC TECHNIQUE

In 1993, I began performing laparoscopic transperitoneal fusion of the lumbar spine and developed this approach along with Dr. David Mahvi, my general surgery colleague. Dr. David Mahvi, my general surgery colleague. The L5–S1 level lends itself to an endoscopic approach because of its easy accessibility between the bifurcation of the great vessels.

- Give a light bowel preparation the night before surgery.
- Facilitate exposure by placing the patient in the Trendelenburg position and allowing abdominal insufflation, which causes the small bowel to drift toward the diaphragm. This precludes the need for retraction of the abdominal contents; thus postoperative ileus is eliminated.
- Usually, the laparoscopic camera is placed in a periumbilical incision.
- Place two 5 mm portals laterally, midway between the umbilicus and the pubis, to allow retraction or suction as needed.
- Finally, place a supracorporeal portal in line with the disc space. At the L5–S1 level, this is often two to three fingerbreadths above the pubic symphysis. At L4–5, it is usually midway between the umbilicus and pubic symphysis.
- Drain the bladder with a Foley catheter before placing this portal.
- The sigmoid colon may need to be retracted toward the left and will usually stay in this position throughout the procedure. The remainder of the dissection proceeds in much the same fashion as previously described (see "Open Transperitoneal Approach" above).

Figure 146.3. Anteroposterior (A) and lateral (B) radiographs of a 39-year-old man with persistent low-back pain. He had a history of remote sciatica, which resolved but has now developed into persistent low-back pain despite maximal physical therapy. These radiographs show classic changes of degenerative disc disease: a narrowed disc space, sclerotic endplates, and marginal osteophyte formation. The L4–5 disc was normal on MRI, and thus no discography was indicated.

Laparoscopic transperitoneal fusion access route. Surgery consisted of anterior discectomy at L5–S1, distraction, and insertion of two tapered (LT) cages (Lumer Tspered, Sofamon Danek, Memphis, TN) at the L5–S1 disc space. Note the restoration of foraminal height and sagittal contour.

Figure 146.4. Laparoscopic transperitoneal fusion access route. Surgery consisted of anterior discectomy at L5–S1, distraction, and insertion of two tapered (LT) cages (Lumer Tspered, Sofamon Danek, Memphis, TN) at the L5–S1 disc space. Note the restoration of foraminal height and sagittal contour.
would agree that the upright carbon fiber cage is not stable enough to be used as a stand-alone device. Fraser (Harms first introduced upright titanium mesh cages. Typically, two upright cylinders of titanium mesh are cut to fit the disc space and then driven into the space to have had success with this technique, others have shown that additional bone grafting is necessary to provide an adequate surface area for healing. In addition, spondylolisthesis with a tall mobile disc space. have been used in patients with degenerative disc disease or spondylolisthesis with a degenerated disc space. I do not recommend the use of cages alone in cases of In general, threaded cages placed anteriorly can restore the stability of the lumbar spine without the need for supplementary posterior fixation. They have successfully placement of a tapered distraction plug. The principles of cage interbody fusion include the following: Disc space distraction to cause tension in surrounding ligamentous structures, which increases stability Preparation of the endplates to expose cancellous bone, as well as providing an endplate substrate for weight bearing Provision of enough bony surface area to heal from one endplate through the bone graft to the other endplate Realignment of the spine to its optimal lordotic sagittal balance Production of a solid, long-term arthrodesis.

With current short-term follow-up, it appears that cage interbody fusion is successful in meeting these goals (13). Several principles must be kept in mind, however, when interbody fusion cages are used. Disc spaces that have not undergone any degree of collapse are difficult to further distract. Therefore, the tall mobile disc space may not be an ideal candidate for cage-only fusion procedures. In addition, forceful distraction is required, and if the endplate bone is not strong enough to resist the distractive force, subsidence and instability will result. For this reason, do not use cages in patients with osteoporosis. Finally, most cage systems are designed for two cages to be implanted side by side. Although some biomechanical studies suggest that a single cage may lead to short-term stability, it is my feeling that there is inadequate surface area to ensure long-term arthrodesis. The RAY cage (Surgical Dynamics, Minneapolis, MN) and the BAK device (Spinetech, Minneapolis, MN) were the initial threaded interbody fusion cages (19). They have been used with both posterior and anterior interbody fusion techniques. When used anteriorly, these systems restore lordosis through patient positioning and the placement of a tapered distraction plug. After the disc space is distracted, prepare the endplate on each side of the disc by passing a reamer to remove endplate cartilage, bone, and disc material. Then tap each side and place two threaded devices. Take great care, when placing cages, to identify the midline of the spine so that cages are not placed eccentrically. Determine the appropriate size cages from the radiographs and preoperative templates. A tapered threaded device has been designed that more accurately matches the anatomy of the L5–S1 disc space. It appears that a greater amount of lordosis can be obtained through the use of tapered cages with a minimal amount of endplate resection (16).

In general, threaded cages placed anteriorly can restore the stability of the lumbar spine without the need for supplementary posterior fixation. They have successfully been used in patients with degenerative disc disease or spondylolisthesis with a degenerated disc space. I do not recommend the use of cages alone in cases of spondylolisthesis with a tall mobile disc space. Lateral cages have been placed both openly and endoscopically in the lumbar spine. Often, a single threaded cylindrical lateral cage is utilized. Although some authors have had success with this technique, others have shown that additional bone grafting is necessary to provide an adequate surface area for healing. In addition, LeHuec (11) designed a combined lateral cage and plate system to increase the rate of fusion. Harm's first introduced upright titanium mesh cages. Typically, two upright cylinders of titanium mesh are cut to fit the disc space and then driven into the space to provide support for the endplate and for healing potential. Harm's recommended that posterior instrumentation be used to supplement ALIF with upright cages. Brantigan and Stelfee (2) designed upright carbon fiber cages. While these were also met with worldwide acceptance and a high degree of success, most authors would agree that the upright carbon fiber cage is not stable enough to be used as a stand-alone device. Fraser (5) recommends that posterior fusion, as well as facet

Figure 146.5. The use of tapered interbody fusion cages at L5–S1 permits the restoration of both height and lordosis. Preoperative (A) and postoperative (B) lateral radiographs demonstrate the lordosis obtained in a 48-year-old man with degenerative disc disease.
screw instrumentation, be utilized to augment the interbody carbon fiber cage.

The use of spinal cages is evolving rapidly. Surgeons must evaluate each patient on an individual basis to determine which particular device is most appropriate.

### PITFALLS AND COMPLICATIONS

Anterior lumbar surgery is never easy and requires adequate surgical planning and preoperative preparation. An accurate understanding of the vascular and neurologic anatomy is a requirement for the performance of these procedures. The assistance of a general or vascular surgeon may be necessary to obtain adequate exposure. Preoperative preparation consisting of a light bowel regime (e.g., GOLYTELY and Fleet enema) will make retraction of intestinal structures easier. Preoperative examination of the patient's abdomen and flank for prior incisions and potential adhesions is necessary. Preoperative evaluation of MRI or computed tomography to assess variations in the vascular anatomy is important, as it directs which approach will be used for the portion of the spine to be fixed.

Vascular complications are certainly the most serious and life-threatening. The incidence of injury to the aorta, vena cava, or iliac vessels is estimated at 1% to 3% for anterior approaches (7, 9). These injuries may be life-threatening and need to be dealt with calmly and with assistance. Obtain immediate control with tamponade. If the procedure is being done endoscopically, immediate laparotomy is recommended.

The assistance of a vascular surgeon is highly recommended for repair of the great vessels. The most common areas of vascular injury are the left common iliac vein at the L5–S1 level and the left side of the vena cava at the L4–5 level. At L4–5, there are several small perforating veins that may come from the posterior surface of the vena cava. They may need to be coagulated and divided before the vena cava is retracted, to prevent their avulsion. As mentioned earlier, control and ligation of the iliolumbar vein will greatly assist in vena cava mobilization.

Arterial occlusion due to embolization of plaques has also been reported (18). Anterior approaches to the lumbar spine in elderly patients are hazardous and must be done only when absolutely necessary and with caution. In many of these patients, the arterial system is much less mobile, and retraction may dislodge plaques. Always do a postoperative vascular examination, and if pulses are absent or the limb is cool, obtain an immediate consultation with a vascular surgeon. Routine anticoagulation has not been found to be necessary in ALIF surgery. However, if a major vessel must be repaired, postoperative anticoagulation may be necessary.

Neurologic complications include damage to the presacral plexus, nerve root injury, and violation of the spinal canal. As mentioned, the parasympathetic nerves that run along the lumbar and sacral plexus are vulnerable to injury. They run along the aorta and vena cava. When the bursa is opened, they pass distally. For work along the L4-5 or L5–S1 disc spaces, it is mandatory that only blunt dissection be used and that no monopolar electrocoagulatery be used. The incidence of retrograde ejaculation following ALIF has been estimated to be from 1% to 4%.

It appears that the incidence of neurologic injury is slightly higher in endoscopic procedures than in the open retroperitoneal approach. Early in any surgeon's experience, there is certainly a higher incidence of retrograde ejaculation. Fortunately, most cases of retrograde ejaculation are temporary and resolve within 4–6 months. It is assumed that they are due to stretch injury that occurs during exposure of the disc space. Should the patient not recover from retrograde ejaculation, urologic consultation is recommended.

The nerve roots are vulnerable after they exit the neuroforamina and proceed toward the psoas muscle. If the midline is not adequately evaluated and fusions are performed far lateral to the disc space, the nerve root is vulnerable to injury. Bone grafts or cages that are placed too laterally or too deeply may impinge on the neuroforamen of the level above. It is imperative to use fluoroscopy at some point to locate the midline of the disc space and maintain orientation as to the right and left margins of the disc space.

Cages or grafts that are placed too deeply may impinge on the spinal canal, causing cauda equina injury. Once again, fluoroscopic control of the implantation of interbody fusion devices should help eliminate this complication.

Abdominal-wall complications related to the approach may occur. The epigastric vessels must be either retracted or controlled, or a postoperative abdominal-wall hematoma may occur. Overzealous retraction of the rectus abdominis may lead to a stretch injury and cause weakness of the abdominal wall. During a flank approach, repair each layer independently to prevent weakening of the abdominal wall.

Pseudarthrosis of an ALIF may occur. Although the incidence of a pseudarthrosis after a 360º fusion is performed is exceedingly low, ALIF alone does carry a risk of pseudarthrosis. With the use of only iliac crest autograft, the pseudarthrosis rate was estimated at 30% to 35% (4, 7). Femoral allograft rings have shown to have a pseudarthrosis rate approaching 20% (12). Threaded cortical bone dowels appear to have a much lower pseudarthrosis rate, but follow-up is too short to be conclusive.

Threaded interbody fusion cages have been reported to have a 90% fusion rate in the early BAK and RAY cage studies (19). Recent reports show a higher pseudarthrosis rate, however, which may be secondary to poor surgical indications or poor surgical technique (15). Should pseudarthrosis occur and the cages or bone dowels remain in an acceptable position, I recommend proceeding with a posterior instrumented fusion at that level. It will often resolve the patient's symptoms and may lead to healing of the interbody fusion. If a cage or bone dowel should migrate and cause neurologic symptoms, it should be removed at the time of revision surgery. Revision anterior interbody surgery is dangerous and should be approached with caution. Vascular structures often become adherent to the previously operated disc space, and the presence of a vascular surgeon is necessary for these challenging cases.

Finally, the incidence of persistent pain after ALIF has been estimated to be 10% to 20%. The exact cause is unknown and may be related to patient selection. This fact alone indicates that the treatment of low-back pain with interbody fusion is evolving. Keep in mind that the exact cause of each patient's low-back pain may be unknown.

### AUTHOR'S PERSPECTIVE

The use of ALIF techniques provides numerous advantages. Restoration of the weight-bearing column, provision of a greater surface for fusion to occur, and the ability to recreate the normal sagittal position of the spine are among its greatest advantages. If complications should occur, however, many of these advantages are lost. To obtain a high clinical and radiographic success rate, strict adherence to the details of the surgical approach and the fusion technique are required.

ASSESSMENT

CLASSIFICATION

The etiology of spinal stenosis is most commonly either congenital (developmental), acquired (degenerative), or a combination of both (Table 147.1). The majority of cases of spinal stenosis are acquired, being caused by degenerative changes occurring in the three-joint complex consisting of the intervertebral disc and the two facet joints. In some cases, such degenerative changes may be superimposed on a pre-existing congenital stenosis. Variations in the shape, as well as the size, of the spinal canal may predispose the patient to spinal stenosis, with a trefoil canal being associated with lateral recess stenosis more commonly than a round or oval canal.

CLINICAL EVALUATION

History

Spinal stenosis is an anatomic description that should not be confused with neurogenic claudication, although the two terms are often used interchangeably. Spinal stenosis refers to morphology, not symptoms. Neurogenic claudication, also known as pseudoclaudication, is a clinical syndrome with symptoms of leg pain that are associated with walking. Neurogenic claudication should also be distinguished from vascular claudication, which has a different etiology and slightly different clinical features.
The pathology of spinal stenosis comprises both a peripheral neuropathy. Findings, such as diminution of pinprick sensation, are uncommon with spinal stenosis. The presence of paresthesias should raise the suspicion of an underlying symmetrically reduced, or absent in the older patient. Therefore, the presence of diminished reflexes is usually not clinically significant unless it is asymmetric. Sensory stretch test, are uncommon with spinal stenosis unless it is associated with a disc herniation. Deep tendon reflexes, particularly at the ankle, may be normal, caused by the variation of canal size with posture

Table 147.2. Vascular Versus Neurogenic Claudication

Table 147.3. Comparative Features of Lumbar Disc Herniation versus Spinal Stenosis

Neurogenic claudication is defined as lower extremity pain, paresthesias, or weakness associated with walking or standing (57). Pain is the predominant symptom, being present in up to 94% of patients, with numbness (63%) and weakness (43%) being less common. Bilateral involvement is common. Patients with neurogenic claudication may present with either unilateral radicular pain or with diffuse, nonradiating symptoms beginning in the buttocks and extending a variable distance into the legs. Radicular pain is typically dermatomal in distribution and is often unilateral. It is the presenting type of symptom in 6% to 13% of symptomatic patients. It is often seen with lateral recess stenosis, foraminal stenosis, or with concomitant disc herniation. The presence of a symptomatic disc herniation in a patient with a narrowed spinal canal and spinal stenosis is not uncommon. Patients with either developmental or degenerative stenosis are more likely to develop symptomatic radiculopathy in the presence of a small disc herniation or even disc bulging (62,94).

Symptoms are typically produced by standing or walking and are relieved by sitting or bending forward (Table 147.2). Patients may preferentially assume a stooped-over posture when walking, or even standing, in order to ameliorate symptoms (5). Other leg symptoms such as weakness or numbness may also occur in anodyne, such as prolonged standing or walking. Night pain is uncommon, although it has been described in patients with lateral recess stenosis (54). Unusual symptoms, such as priapism associated with intermittent claudication during walking, have also been reported.

The relationship of symptoms to posture can be explained by the variation of canal size with posture (5,47,122). Cadaveric studies have demonstrated that the spinal canal cross-sectional area, midsagittal diameter, and subarticular sagittal diameter are significantly reduced in extension (standing) and are increased with flexion (sitting) (47). Associated neural compression was also found to be greater in extension than in flexion (47).

In vivo studies relating posture to epidural pressure measurements have shown that epidural pressures at the level of stenosis were higher in the standing posture compared with those in the lying and sitting postures. Furthermore, local epidural pressures were increased with extension and decreased with flexion (47).

Neurogenic claudication should be distinguished from vascular claudication (Table 147.2). Although both conditions may present with leg pain associated with walking, it is only patients with neurogenic claudication who have leg pain resulting from standing. Leg pain associated with neurogenic claudication is highly position dependent. Vascular claudication, on the other hand, is unaffected by positions of lumbar flexion or extension. Leg pain from vascular claudication may be produced by cycling in a sitting position (27). Patients with vascular claudication typically have leg pain while walking uphill, whereas patients with a neurogenic etiology do not have this pain owing to the slightly flexed posture of the lumbar spine associated with this activity. Patients with neurogenic claudication may actually have increased leg pain when walking down an incline owing to increased associated lumbar lordosis.

A summary of the pertinent historical features of spinal stenosis are listed below:

- Demographics
  - Typically middle aged or older, unless congenital
  - Female > male (3:1 to 5:1)
  - Leg pain > LBP
  - May have long history of antecedent LBP
  - Leg pain
    - Refferred or radicular
    - Pseudoclaudication (neurogenic claudication)
      - Provoked by standing or walking
      - Relieved by sitting or leaning ("grocery cart sign")
    - Differential diagnosis
      - Peripheral neuropathy (not activity related; burning dysesthesia)
      - Vascular claudication versus neurogenic claudication (Table 147.2)
      - Hip arthropathy ("Hip-spine syndrome")

Physical Examination

Begin the examination of the patient with spinal stenosis by observing the patient, both at rest and during walking. Because symptoms are typically induced by the normal lordotic posture associated with walking or standing, the patient often preferentially assumes a slightly flexed posture in order to relieve neural compression causing leg pain. Flattening of the lower lumbar spine, owing to reduction in lumbar lordosis, may also be observed. With progressive ambulation, the patient may become increasingly more kyphotic in posture. This represents a conscious, or subconscious, attempt to decrease root compression by increasing canal or foraminal size. Back range of motion will likely be reduced as a result of age-related arthritis.

Lumbar spinal stenosis is usually unaccompanied by hard neurologic signs (Table 147.3) (5,57,102). Tension signs, such as straight leg raising sign or femoral nerve stretch test, are uncommon with spinal stenosis unless it is associated with a disc herniation. Deep tendon reflexes, particularly at the ankle, may be normal, symmetrically reduced, or absent in the older patient. Therefore, the presence of diminished reflexes is usually not clinically significant unless it is asymmetric. Sensory findings, such as diminution of pinprick sensation, are uncommon with spinal stenosis. The presence of paresthesias should raise the suspicion of an underlying peripheral neuropathy.

The pathology of spinal stenosis comprises both a fixed, anatomic lesion as well as a dynamic component. Because of the dynamic nature of spinal stenosis,
Symptoms or objective neurologic findings are not usually elicited until these dynamic factors are invoked. Therefore, resting neurologic examination is usually normal. The most common neurologic finding is weakness of the extensor hallucis longus (EHL). Patient symptoms may sometimes be provoked by either walking or lumbar hyper-extension. Indeed, reproduction of leg pain by hyperextension of the back may be the only objective finding (5). Signs and symptoms may also occasionally be elicited by examining the patient immediately after walking to the point of producing leg pain. Unusual weakness, mild muscle weakness or loss of sensation of a tendon reflex may be detected. Profound muscle weakness is uncommon unless stenosis is accompanied by concomitant disc herniation. Long tract findings of spasticity, hyperreflexia, and clonus suggest superimposed cervical or thoracic myelopathy.

When examining the patient, rule out other potential causes for leg pain such as hip arthropathy or peripheral vascular disease. Include an examination of peripheral pulses and an examination of the hip. In addition to reproduction of the patient's pain by hip range of motion, the presence or absence of a hip flexion contracture should also be determined because its presence may not only help explain a patient's symptoms but also has therapeutic implications.

**Radiographic Evaluation**

Correlate the objective clinical findings with the radiographic findings in order to determine the significance, if any, of the radiographic finding and the patient's symptoms. Precise correlation between objective clinical findings and diagnostic imaging has been shown to have a high positive predictive value for good clinical outcome in patients undergoing surgery for symptomatic lumbar disc herniation. This poses somewhat of a problem in the diagnosis of lumbar spinal stenosis, in which objective neurologic findings are usually absent and the clinical diagnosis is made by patient symptoms rather than clinical findings (63).

Overemphasis on the radiographic component of patient evaluation can lead to a poor outcome following surgery, because radiographic abnormalities, including neural compression, are found in a significant proportion of asymptomatic individuals (13,45a,50,120). Unless there is concern for the presence of tumor or infection, avoid diagnostic imaging when the history or objective clinical findings do not support a compressive or mechanical cause for the patient's pain. Extensive diagnostic imaging can be delayed until the patient is a clear candidate for surgery.

**Conventional Radiography**

Plain radiography is insensitive in predicting symptoms of either LBP or radicular leg pain (37,71). It has been estimated that only one in 2,500 lumbar radiographs yields clinically unsuspected findings in patients 20 to 50 years of age. Numerous studies have reported age-related degenerative x-ray changes to be present equally in both asymptomatic and symptomatic populations (37). Only the study by Frymoyer et al. (32) reported a statistically significant correlation between symptoms and any degenerative finding, that being an association between LBP and disc space narrowing or traction spurs at the L4–L5 interspace only.

Plain radiography is still an important preoperative tool. Obtain radiographs in all patients undergoing surgery for spinal stenosis. Look for unsuspected bony pathology, such as spinous bifida occulta, on plain radiographs of patients undergoing lumbar surgery. In addition, the presence of transitional vertebrae should be identified when present, thereby alerting the surgeon to the possibility of errors in intraoperative localization.

Obtain standing lumbar x-ray studies for all patients undergoing surgical decompression for spinal stenosis to identify unrecognized degenerative spondylolisthesis or degenerative scoliosis, which could be undetectable on supine films. Preoperative identification of such pathology may influence the type of the planned surgery, such as the need for concomitant fusion with decompression. Furthermore, failure to identify a pre-existing degenerative spondylolisthesis preoperatively might lead to the erroneous conclusion that a slip seen on a postoperative x-ray study is iatrogenic.

**Dynamic Radiography (Flexion-extension X-ray Studies)**

Many authors believe that dynamic radiographs are more useful than static x-ray studies in making a radiographic diagnosis of instability (14,41,81). Even with these radiographs, however, there is no uniformly accepted method of measurement of such instability (105). Shaffer et al. reported that the Morgan and King method of measuring translation (105). Other authors have described angulation, in addition to translation, as being indicative of radiographic instability (14,41).

As with routine radiographs, there exists a spectrum of normal translation and angulation that can exist in the absence of symptoms (14,41). Over 90% of asymptomatic volunteers exhibit between 1 and 3 mm of translation on flexion extension radiographs, and the mean dynamic sagittal rotation from flexion to extension ranges from 7.7° to 9.4° at each lumbar level (13). For translation, a dynamic change of greater than 4 mm is considered abnormal. Because plain radiographs do not visualize neural structures, they generally fail to provide an explanation for radicular pain.

**Myelography**

As opposed to computed tomography (CT) or magnetic resonance imaging (MRI), both of which directly visualize neural compression, myelography provides indirect evidence of nerve root compression by demonstrating changes in the contour of normal contrast-filled structures. As such, the exact nature of compression can be unknown and could thus occur at multiple levels or from different levels. For example, result in diagnostic confusion. Preoperative identification of such pathology may influence the type of the planned surgery, such as the need for concomitant fusion with decompression. Furthermore, failure to identify a pre-existing degenerative spondylolisthesis preoperatively might lead to the erroneous conclusion that a slip seen on a postoperative x-ray study is iatrogenic.

Another advantage of myelography over CT or MRI is its superior ability to visualize neural compression associated with scoliosis afforded by its coronal imaging capabilities. The presence of a three-dimensional deformity such as scoliosis makes visualization of neural compression by CT or MRI more difficult than with myelography.

Because the dura ends at the level of the dorsal root ganglion (DRG) (21), which is located at the level of the pedicle, myelographic dye cannot extend beyond that point and myelography is unable to detect foraminal disc herniations, lateral stenosis, or the so-called far out syndrome, which is diagnosed more accurately by CT or MRI (121). The far-out syndrome typically occurs in the elderly patient with degenerative scoliosis or in the younger patient with a grade II or higher isthmic spondylolisthesis. The L-5 nerve root is compressed far laterally by either the L-5 transverse process or kinking beneath the L-5 pedicle.

Another disadvantage of myelography over CT is its inability to detect pathology below the level of a complete block to dye flow (43). This may occur in cases of severe spinal stenosis, such as with a high-grade L4–L5 degenerative spondylolisthesis. Under such circumstances, dye must be introduced both below and above the level of the block, or as is more commonly done, an adjunctive study such as MRI or CT must be used (43).

Postoperative imaging of the instrumented spine by CT or MRI is difficult owing to significant metal artifact associated with the use of stainless steel spinal instrumentation. This problem is partially obviated by the use of myelography, which is not associated with image distortion.

Hildebrandt and Witten reported that 24% of asymptomatic patients undergoing oil-based contrast studies for suspected acoustic neurilemmoma had abnormal lumbar myelography (45a). This finding underscores the importance of correlating radiographic abnormalities with clinical findings. The reported accuracy of water-soluble nonionic lumbar myelography in the diagnosis of lumbar nerve root compression ranges from 67% to 100%, depending on the criteria employed for diagnosing nerve root compression, whether or not surgical confirmation of compression was used as the standard, and whether or not the tests were interpreted without knowledge of clinical symptoms or objective neurologic findings (19,41,48,49,119). Most studies report the diagnostic accuracy of myelography for spinal stenosis to be between 70% and 90%.

**Computed Tomography and Postmyelography Computed Tomography**

Unlike myelography, CT visualizes the neural structures directly, and therefore provides more accurate knowledge of the nature of the compressing lesion. Advantages of CT over myelography include its noninvasive nature, less ionizing radiation, and a better ability to visualize lateral pathology such as lateral or foraminal disc herniation or foraminal stenosis. Because CT is usually performed without sagittal reformation, it provides imaging in only one plane and routinely images only a limited segment of the spine. Therefore, CT misses proximal lumbar pathology, such as a high-grade spondylolisthesis, focal spinal stenosis, or other significant pathology (e.g., a thoracolumbar tumor) unless it is specifically oriented to those levels. Because spinal stenosis is a global condition, commonly involving upper lumbar segmental levels as well as lower lumbar levels, routine use of only CT as the primary imaging tool would result in some missed diagnoses.

As with routine radiography and myelography, lumbar CT abnormalities are common in asymptomatic subjects. Wiesel et al. (120) reported that 35.4% of asymptomatic individuals in their study group had an abnormal CT scan. Reported accuracy of CT in the diagnosis of nerve root compression from disc herniation or stenosis ranges from 66% to 100% (19,48,49,119).

The accuracy of CT can be enhanced by the simultaneous use of water-soluble contrast agents (intrathecal contrast-enhanced CT or myelo-CT). The incremental benefit provided by combining both procedures is so great that they are usually performed sequentially as a part of a single study for spinal stenosis. Postcontrast CT
allows distinction between the disc margin, thecal sac, and ligamentum flavum, three structures that can blend together in a tight spinal canal, which is a normal tissue-separating fat is absent. It is invaluable in visualizing a stenotic spine associated with a complete myelographic block, as in severe lumbar stenosis associated with degenerative spondylolisthesis (43). Correlation between contrast-enhanced CT and myelography ranges between 75% and 96%, with myelo-CT invariably being the more accurate study (43,48,49,112).

Magnetic Resonance Imaging MRI: the spine is imaged by the matrix of sequences that have been assigned a shade of gray based on the intensity of a radio wave signal emanating from the tissue (7,9). In the lumbar spine, T1-weighted sagittal and axial sequences of approximately 4 mm slice thickness and sagittal gradient echo (GE) sequences are performed most commonly. Typically, osseous structures appear as areas of relative signal void, with cortical bone having a low intensity on MRI, and cancellous bone having a higher signal intensity owing to its fat content. The distinction between small cortical bone osteophyte and a small disc herniation on T1-weighted sagittal image may be difficult, and precise differentiation between the two features may require CT. The nucleus pulposus is best visualized by T2-weighted spin echo (SE) sequences, which reflect the degree of hydration of the disc. With aging and disease, there is decreased signal intensity due to changes in total hydration within the disc (13). The T2 image tends to overemphasize the size of a disc herniation and, therefore, can overestimate its potential significance.

MRI, like myelography, can image the entire spine and can detect unsuspected pathology such as high-lumbar disc herniation, proximal stenosis, or thoracolumbar spinal tumor. MRI is noninvasive and eliminates the potential risk and associated discomfort associated with myelography. Like CT, MRI visualizes the spine directly, providing detail as to the etiology of neural compression and accurately image lateral pathology. Unlike routine CT, however, MRI provides sagittal visualization of the spine and therefore provides imaging in orthogonal planes. Furthermore, MRI uses parasagittal views, which provide sequential visualization of neural foramina and can detect foraminal entrapment beyond routine CT. This feature is particularly valuable for imaging spinal stenosis, in which neural entrapment within or beyond the neural foramen can be well visualized. MRI distinguishes between the disc and neural tissue better than nonenhanced CT but generally does not distinguish between bony and soft-tissue compression as well as CT. When this distinction is deemed important, as it sometimes is in cases of spinal stenosis, CT or contrast-enhanced CT is sometimes needed.

As with plain radiography and CT, abnormal MRI findings are common in asymptomatic individuals. In one study of asymptomatic subjects, the lumbar MRI images of 22% of those younger than age 60 and 57% of those older than age 60 were abnormal, showing disc herniation or spinal stenosis (53). Approximately 90% of those older than 80 years of age showed some element of lumbar disc degeneration, as demonstrated by decreased signal on T2-weighted images. The reported accuracy of MRI, when compared with documented intraoperative lumbar nerve root compression, is comparable to that of contrast-enhanced CT (myelo-CT) (49,49).

**NATURAL HISTORY**

The true natural history of spinal stenosis is unclear, because good studies documenting the course of nontreatment are lacking. This is partly because most patients with this condition receive some form of conservative or surgical treatment, and those with severe stenosis are ultimately operated on (32). Several reported studies have described the clinical features of spinal stenosis, or its surgical treatment, and have included some patients who received no treatment (51). Approximately 20% of those receiving no treatment experienced progression of their symptoms.

The largest and best study of the natural course of lumbar spinal stenosis was published by Johnsson et al. (52), who reported on 32 patients with spinal stenosis followed for an average of 49 months. These patients were described as having “conservative treatment (i.e., no treatment)” because either the patient refused to undergo surgery or the anesthesiologist refused to administer anesthesia. Therefore, these patients had indications for surgery but were not operated on. At final follow-up, based on the clinical examination, 41% of patients were improved and 18% were worse. Based on subjective symptoms, only 15% were improved and 15% were worse. Changes in the patients’ walking capacities were equally distributed among improved, worse, and unchanged (Table 147.4). When the final outcome was compared with the anteroposterior (AP) diameter of the dural sac, as measured on water-soluble contrast myelography, patients with narrow AP diameters had a tendency not to improve. This study concluded that the majority of patients with spinal stenosis who did not undergo surgery remained unchanged at 4 years of follow-up and severe progression was unlikely.

**Table 147.5. Comparison of Surgical Versus Nonsurgical Treatment of Lumbar Spinal Stenosis**

A recent attempt at meta-analysis of the literature on surgery for spinal stenosis failed to identify a single randomized trial comparing surgery with conservative treatment (113). A recent report evaluating the outcome of patients treated with a variety of surgical measures (therapeutic exercises and epidural steroids, if necessary) suggested that such treatment could be very effective (103). Fifty-two patients were followed for 2 to 8 years. Thirty-three patients (63%) reported a tolerable pain level without major restriction in daily activities or use of narcotic analgesics; 36 patients (69%) reported “no or minimal restriction in walking tolerance,” although 25 patients (48%) reported “difficulty in standing for long periods.” None of the patients experienced any neurologic loss. Four of the 52 patients (8%) required surgery for presumed failure of nonsurgical measures. The exclusion criteria for this study included patients with pre-existing disease (comorbid conditions) or with a “compliance issue that prevented participation in a therapeutic exercise program.” In addition, it did not compare conservative treatment methods with surgery and could not, therefore, offer any comparative data regarding optimal treatment of this condition.
SURGICAL TECHNIQUES

Surgery for lumbar spinal stenosis may be broadly divided into decompressive procedures without concomitant fusion and decompression with fusion. Surgical decompression may vary from limited procedures, such as single-level unilateral laminotomy for focal neural compression, to global procedures, such as multilevel bilateral laminectomy with bilateral facetectomies. Types of fusion procedures include anterior lumbar interbody fusion (ALIF), posterior lumbar interbody fusion (PLIF), posterior fusion, posterolateral (also known as intertransverse or bilateral lateral) fusion, or combinations of these procedures (see Chapter 145 and Chapter 146). Indirect neural decompression may occur following ALIF or PLIF if disc-space distraction occurs, thereby enlarging the central or foraminal canal. Fusion may be augmented by the use of spinal instrumentation, either anterior fixation devices or posterior structures such as those using pedicle screw fixation.

COMORBIDITY AND SURGICAL OUTCOME

Comorbidity refers to the presence and severity of conditions other than the disorder under study or treatment (56). The relationship between comorbidity and outcome is more commonly applied to surgical than to medical outcomes. Comorbidity typically increases with age and is associated with a poor outcome for many medical and surgical conditions (20,25,107). Sick people have a higher mortality rate, a higher complication rate, and a lower level of function than do healthy patients. It is imperative to take this factor into account when assessing and comparing outcomes between treatment groups. If such factors are not taken into account, differences in outcome between treatment groups could reflect differences in patient comorbidities rather than differences as a result of treatment.

Rates of hospital morbidity and mortality following lumbar spinal surgery are greater with increasing age of the patient (25). Complications are more frequent with advancing patient age, increasing the complexity of both diagnosis and surgical treatment. The study by Deyo et al. (25) reported an overall mortality of 0.07% for 18,122 hospitalizations between 1986 through 1988. The mortality increased with age, increasing to 0.6% (ninefold increase) in patients older than 75 years of age. The overall complication rate of 9.1% increased to 17.7% in patients 75 years of age or older. As would be expected, an increase in comorbidity is often associated with more in-hospital complications and perioperative mortality. This finding is independent of age alone. Oldridge et al. (86) found an age-related increase in mortality only for patients older than 80 years of age. There was, however, a significant increase in in-hospital and 1-year cumulative mortality associated with increasing number of comorbidities.

In a retrospective review of 88 patients undergoing laminectomy for spinal stenosis, Katz (56) concluded that the long-term outcome was generally less favorable than had been previously reported (Table 147.6). By 1 year after surgery, 8% of patients had a second operation and, by the time of the last follow-up, 17% had a repeat surgery. Only 40% of patients with the highest comorbidity score had a good outcome at the time of final follow-up compared with 75% of patients who had the lowest comorbidity score (P = 0.004). The most common comorbidities were osteoarthritis (32%), cardiac disease (22%), rheumatoid arthritis (10%), and chronic pulmonary disease (7%). Their data suggested that the effect of comorbidities was additive, because no single comorbidity was significantly associated with worse outcome. In a subsequent study by the same authors, comorbidity was found to be the second most important determinant of disability in lumbar canal stenosis, with complaints of predominantly LBP (as opposed to leg pain) preoperatively being the most important contributor to disability (55-58).

LAMINECTOMY

The gold standard surgical procedure for spinal stenosis is decompressive laminectomy. This procedure may involve either bilateral laminectomy or hemilaminectomy. For bilateral laminectomy, the lamina and ligamentum flavum are removed on both sides of the stenotic level or levels to the lateral recess. Decompression begins at the most distal extent of neural compression and proceeds in a caudal-to-cranial direction. Although the LS–S1 level is rarely compressed centrally, owing to the capacity of the spinal canal at that level, decompression is most safely initiated at that level rather than at L4–L5, the most commonly involved level, which is often severely stenotic. Perform decompression sequentially, from medial to lateral.

- Position the patient in a kneeling position to allow the abdomen to hang freely in order to reduce abdominal compression and thereby reduce epidural bleeding. Prepare and drape the lumbosacral spine and expose the posterior elements from facet joint to facet joint laterally along the entire length of the intended decompression.
- Begin with a midline decompression. This is generally performed from the left side of the operating table (i.e., on the patient's left side) for a right-handed surgeon and on the right side by a left-handed surgeon.
- Use either 45° or 90° Kerrison rongeurs. In areas where stenosis is not severe, use a relatively large rongeur, such as a 4 mm Kerrison rongeur, to remove the thickened lamina.
- Maintain proper orientation during the procedure by identifying the level of the pedicle, because this defines the level of the nerve root. If in doubt as to the proper level, confirm with an intraoperative radiograph with a bent probe beneath the pedicle, within the neural foramen.
- Decompress the lateral recess next. Extend the decompression laterally until the lateral edge of the root is visualized and determined to be free of pressure. Take care to preserve the pars interarticularis to minimize the risk of producing instability by inadvertent sacrifice of the superior articular facet. Preserve the facet joint by using oblique-angled (45°) Kerrison rongeurs or by the use of osteotomes to undercut the facet joint (39,104).
- Finally, perform lateral decompression of the foraminae. Once the shoulder of the nerve root is identified and decompressed, follow it from its origin through the foraminar space.
- It is generally safer to proceed in a cranial-to-caudal manner in order to minimize risk of inadvertently cutting across the root, which can occur when performing the lateral decompression from a distal-to-proximal direction. Occasionally, the use of a right- or left-angled Kerrison rongeur can be helpful for foraminal decompression.
- Assess the adequacy of decompression within the neural foramen both visually and by palpation. Use a bent probe, such as a bent #4 Penfield elevator or a properly contoured ball probe, to determine the presence or absence of nerve root compression within the neural foramen. Decompression is generally complete when a bent probe can be passed out the foramen both dorsal and ventral to the nerve root, and the root can be gently retracted approximately 1 cm medially.

Following midline and lateral decompression, check for the presence or absence of a concomitant disc herniation, which might contribute to neural compression. Such herniations may be located either posterolaterally, foraminally, or extraforaminaly. Unless the disc is contributing to definite neural compression, it is generally best to avoid discectomy in the presence of laminectomy because subsequent instability is more likely to occur when both anterior and posterior supporting structures are violated. When laminectomy is accompanied by discectomy, consider performing an arthrodesis at the time of surgery.

Because spinal stenosis is a global degenerative process, encompassing multiple levels and involving nerve roots bilaterally, multilevel bilateral laminectomy is commonly required. There is, however, some debate as to whether it is more appropriate to decompress only the symptomatic level and side, or whether all stenotic

Standard modalities commonly employed to treat spinal stenosis include nonsteroidal anti-inflammatory medications, analgesics, oral and epidural steroids, physical therapy, bracing, and calcitonin (109).
levels should be decompressed. The argument against decompression of asymptomatic root levels or sides is the risk of producing symptoms at a previously asymptomatic level or side. On the other hand, failure to decompress a stenotic but asymptomatic level or side risks progression of the degenerative process with the development of more severe and potentially symptomatic stenosis. In addition, the natural tendency for degenerative changes to progress over time makes it possible that, in time, asymptomatic stenotic levels will eventually become stenotic. Indeed, several studies have reported long-term deterioration following initially successful surgical decompression (18,19,66,80,90,91 and 92).

HEMILAMINECTOMY

Hemilaminecetomy involves unilateral, rather than bilateral, removal of bone and ligamentum flavum. Because the spinous processes, interspinous ligaments, and supraspinous ligaments are preserved medially, normal stabilizing structures are retained with less risk of development of postoperative instability. Take care to preserve the pars interarticularis laterally in order to minimize risk of postoperative instability (15,106). Hemilaminecetomy is appropriate for patients with unilateral symptoms from stenosis. A disadvantage of this procedure is the relative difficulty of performing contralateral decompression and also in obtaining enough medial exposure to perform an adequate ipsilateral decompression in patients with foraminal stenosis. The presence of an intact spinous process and interspinous or supraspinous ligament complex makes it difficult to angle the Kerrison rongeur laterally enough to insert the jaw of the rongeur into the depths of the neural foramen. Under such circumstances, removal of the midline spinous process and interspinous or supraspinous ligament complex may be necessary in order to allow the proper angulation of the rongeur to perform the foraminal decompression. In addition to preserving midline stabilizing structures, hemilaminecetomy also avoids exposure of, and potential injury to, the contralateral facet joint. Because the integrity of the unexposed contralateral facet is maintained, more aggressive decompression of a nerve root by partial, or even total, ipsilateral facetectomy need not necessarily be accompanied by a fusion.

Contralateral nerve root decompression may be accomplished through a unilateral hemilaminecetomy approach by tilting the table away from the operating surgeon (Fig. 147.1). Particularly when used in conjunction with an operating microscope, which provides excellent illumination and which can be angled to visualize the opposite side, contralateral decompression can be accomplished without the need for removal of stabilizing midline structures (spinous processes and interspinous or supraspinous ligaments). The contralateral neural foramen can be visualized and decompressed, and its more distal portion can be palpated with a long bent probe such as a #4 Penfield elevator or a contoured probe. Although offering the advantage of preserving normal, noncompressing midline structures and minimizing scar tissue on the opposite side, this technique is more demanding than bilateral laminectomy because decompression is performed through a more limited exposure and the determination of adequate foraminal patency is more dependent on feel (palpation) than by direct visualization. In addition, there is a greater potential for dural laceration from the Kerrison rongeur when working through a small opening. Should such a dural tear occur, its repair often necessitates complete (bilateral) laminectomy with adequate exposure of the dural rent.

RESULTS OF DECOMPRESSIVE LAMINECTOMY

A recent review of the literature for spinal stenosis surgery failed to identify even a single randomized trial comparing surgery and conservative treatment (Table 147.7) (113). Turner et al. (113) attempted a meta-analysis of the literature on surgical outcomes for spinal stenosis, but the poor scientific quality of the literature precluded the authors from conducting the intended meta-analysis. Even using the authors’ own ratings, the average proportion of good-to-excellent outcomes was only 72%. This study found no statistically significant relationship between outcome and patient age, gender, presence of prior back surgery or number of levels operated on. In those studies reporting on only patients with degenerative spondylolisthesis, the outcome was better. There was no statistically significant difference in outcome between decompression with or without associated fusion. This observation is particularly significant in light of the reported increased morbidity associated with lumbar fusion (114).

Table 147.7. Results of Decompression of Spinal Stenosis without Fusion: Meta-Analysis of Literature 1970–1993 (11 Articles)

In contrast, the prospective cohort study of Atlas et al. (3) reported the 1-year outcome of patients with spinal stenosis treated surgically or nonsurgically in the state of Maine and found that at 1 year, 55% of the surgical patients reported definite improvement in their predominant symptom, compared with only 28% of the nonsurgical group. Surgery was found to increase the relative odds of “definite improvement” 2.6 fold compared with nonsurgical treatment.

In a large retrospective series Katz et al. (60) followed 88 patients for a period of 2.8 to 6.8 years (Table 147.8). Outcome assessment included a questionnaire in which the patients rated their outcomes in terms of pain and function. The authors reported a surprisingly high failure rate, with 11% of patients reporting a poor outcome at 1 year and 43% reporting poor outcome at final follow-up. Six percent of patients had repeat lumbar surgery within the first year and 17% had additional surgery by the time of last follow-up. The authors concluded that the long-term outlook for patients undergoing decompressive laminectomy for spinal stenosis is guarded owing to progressive deterioration of the results over time. They suggested that more extensive bone removal may be indicated at the time of initial surgery.

The authors also reported a high initial success rate following surgery, but by 5 years, the failure rate had reached 27%, with a predicted failure rate of 50% within the anticipated life expectancy of most patients. More than half (62%) of these failures were due to subsequent neurologic symptoms, with an equal incidence of recurrent stenosis at the same level and stenosis at a new level. Because of the high rate of failure from recurrent stenosis, the authors recommended that all levels of impending stenosis be decompressed along with the symptomatic levels.

ALTERNATIVES TO LAMINECTOMY

Despite the fact that some studies report deterioration of standard bilateral decompressive laminectomy over time, more limited alternatives to decompressive
Degenerative spondylolisthesis was first described in 1930 by Junghanns who coined the term pseudospondylolisthesis to describe the presence of forward slippage of a vertebral body in the presence of an intact neural arch (54a). The clinical and pathologic features of this entity were further defined by Macnab, who described the condition as “spondylolisthesis with an intact neural arch” (70). The term degenerative spondylolisthesis was originally used by Newman and Stone and is the terminology most commonly used to describe the anterior slippage of one vertebral body on another in the presence of an intact neural arch (64a).

Degenerative spondylolisthesis may be a source of both LBP and leg pain and may contribute to radicular or referred leg pain in a characteristic pattern of neurogenic claudication (36). The diagnosis is typically made on lateral radiographs, but it may have a dynamic component to it such that the slip may reduce in the supine position and, therefore, may be readily apparent only on stress radiographs. Such radiographs may include standing lateral views, sitting or standing flexion-extension views, or distraction compression radiography (14.41).

As with spinal stenosis generally, little is known of the natural history of degenerative spondylolisthesis. Mardjetko et al. (54a) presented a study of 40 patients who received no treatment and who were followed for at least 5 years (range: 5 to 14 years; mean: 8.25 year). Progressive slip was noted in 12 patients (30%), although no correlation was noted between slip

<tr>
<td>Like hemilaminotomy, contralateral decompression with preservation of spinous processes and midline supraspinous or interspinous ligaments can be performed by tilting the operating table away from the surgeon and by undercutting the medial and contralateral ligamentum flavum with a 45° Kerrison ronguer.</td>
</tr>
</tbody>
</table>

Wide fenestration is a procedure described for central stenosis in which only the medial portion of the inferior facets and adjacent ligamentum flavum is removed (69, 83, 123). Care is taken to remove only pathologic anatomy and to preserve the interspinous or supraspinous ligament complex and spinous processes, which make up the midline stabilizing structures. This may be performed by using bilateral laminotomies at one or more segmental levels, removing the ligamentum flavum (Fig. 147.2A). In a 5-year follow-up study of this procedure, 82% of patients had good or excellent early surgical outcomes, but results deteriorated to 71% satisfactory by 4 years postoperatively (63).

Laminoplasty is an alternative to laminectomy that was originally advocated for active manual workers (76, 77). This procedure is similar to cervical laminoplasty and involves hinging open the lamina on one side and inserting the excised spinous processes into the open hinge in order to keep it patent. There is not sufficient experience with this technique to provide outcomes assessment.

LAMINECTOMY AND FUSION FOR SPINAL STENOSIS

The role of fusion in the treatment of spinal stenosis is somewhat controversial. For stenosis not associated with degenerative spondylolisthesis or other deformity, most studies report that simple decompression is the preferred method of surgical treatment. For patients with associated degenerative spondylolisthesis, concomitant fusion is generally recommended (30, 44). The issue of using supplementary spinal instrumentation is yet unresolved (32, 125).

In a recent prospective, randomized study of 45 patients undergoing either decompression alone or decompression with fusion for spinal stenosis without associated instability, there was no significant difference in outcome between fused and unfused groups (Table 147.8) (45). Overall, 78% of patient-reported and 80% of examiner-rated results were rated very good or good. When broken down by type of procedure performed, there were no significant differences in outcome between the three groups with regard to pain relief. The authors concluded that surgical decompression improved the majority of patients, but further research is needed to determine the natural history of spinal stenosis, resulting in generally favorable outcome and improved quality of life in the majority of patients. They further concluded that arthrodesis was not justified in the absence of radiographically proven segmental instability because there was no statistical difference in outcome between the three treatment groups.
progression and worsening of symptoms. Only 4 of 40 patients (10%) showed clinical deterioration over the course of the study, all of whom were in the group of 28 patients showing no slip progression over the follow-up period. Interestingly, none of the 12 patients with slip progression deteriorated clinically. Therefore, the majority of the patients in this study showed a slight improvement in their clinical symptoms over time, although only 1/3 were felt to have satisfactory function at final follow-up.

### RESULTS OF DECOMPRESSION WITHOUT FUSION

Although current thinking generally favors concomitant fusion for spinal stenosis associated with degenerative spondylolisthesis, decompression without fusion is also a viable therapeutic option (Table 147.10) (78). Overall, 69% of patients from Martinjek’s meta-analysis reported satisfactory outcome with decompression without fusion, with 31% having an unsatisfactory result and 31% having progression of their slip. There was generally no correlation between clinical outcome and amount of slip progression except in the study by Bridwell et al., which showed a positive correlation between the two (15).

Poor surgical outcome following laminectomy without fusion was reported in the prospective randomized study by Herkowitz and Kurz (44) comparing decompression alone with combined decompression and noninstrumented fusion (Table 147.11). In the decompression group, only 11 of 25 patients (44%) had a satisfactory result. This group of patients was found to have significantly more LBP and leg pain than their fused counterparts. Furthermore, the mean slip increased from an average of 5.3 mm preoperatively to 7.9 mm postoperatively. Other authors have reported a similar experience (15,30).

Furthermore, the mean slip increased from an average of 5.3 mm preoperatively to 7.9 mm postoperatively. Other authors have reported a similar experience (15,30).

### RESULTS OF DECOMPRESSION WITH NONINSTRUMENTED FUSION

The role of fusion in the surgical treatment of spinal stenosis associated with degenerative spondylolisthesis is less controversial than the role of fusion in the treatment of other degenerative back conditions (80,113). Capuy and Luesenhop (18) reported a retrospective review of 96 patients undergoing decompressive surgery for spinal stenosis who were followed for at least 5 years. The treatment failed in 16 patients because of recurrent neural involvement, and it failed in 10 patients because of LBP (total failures = 36). The authors concluded that because of the higher incidence of recurrent symptoms in patients with pre-existing degenerative spondylolisthesis, all patients with an associated slip should undergo fusion of the listhetic level.

In their prospective and randomized study comparing decompression alone with decompression and noninstrumented spinal fusion in the treatment of degenerative spondylolisthesis with spinal stenosis, Herkowitz and Kurz (44) reported superior results when concomitant fusion was performed with the decompression (Table 147.11). The reported outcome for the arthrodesis group was excellent in 44% and good in 52% (96% excellent or good total results), whereas in the nonarthrodesis group, only 8% reported an excellent outcome and 36% reported a good outcome (44% excellent or good total results) (P = 0.0001). There was a significant increase in the preoperative slip in patients not receiving an arthrodesis compared with those undergoing fusion (P = 0.002). Interestingly, 36% of those undergoing attempted arthrodesis were noted to have a pseudarthrosis, all of whom had either an excellent or a good result. This study concluded that the results of surgical decompression with in situ arthrodesis are superior to those of decomposition alone. The authors further concluded that the decision for concomitant arthrodesis should be based purely on the presence or absence of a preoperative slip rather than on other preoperative factors, such as the age or sex of the patient or the disc height, or on intraoperative factors such as the amount of bone resected during the decompression.

The prospective randomized study by Bridwell et al. (15) included a subgroup of 11 patients undergoing decompression and noninstrumented fusion. Of the 10 patients...
available for follow-up, only 3 (30%) reported improved functional outcome and seven had an increase in their preoperative spondylolisthesis.

Postacchini and Cinotti (90) reported on bone regrowth occurring an average of 8.6 years after surgical decompression for spinal stenosis (92). Although all 16 patients with degenerative spondylolisthesis showed some bone regrowth, the degree of regrowth was more severe in the six patients who did not undergo arthrodesis. Furthermore, the proportion of satisfactory results was significantly higher in patients who had spine surgery plus arthrodesis (Table 147.12). Although this study was nonrandomized and retrospective, it suggested that arthrodesis stabilizes the spine, resulting in less bone regrowth and superior long-term results.

RESULTS OF DECOMPRESSION WITH INSTRUMENTED FUSION

Zdeblick (124) reported a prospective and randomized study of 124 patients undergoing either instrumented or noninstrumented fusion for a variety of diagnoses. The overall fusion rate for the noninstrumented group was 65%, for the semirigid fixation group, the fusion rate was 77%; and for the rigid fixation group, it was 95%. A trend for better clinical outcome with increasing rigidity of fixation was also observed. Seventy-one percent of the noninstrumented patients, 89% of the semirigid group, and 95% of the rigid group reported excellent or good results. For the subgroup of patients with degenerative spondylolisthesis, 65% of the noninstrumented patients fused compared with 50% of the semirigid fixation group, and 86% of the rigid fixation group had a good or excellent result. Subsequent studies have also reported superior results with concomitant arthrodesis and fusion for spinal stenosis with degenerative spondylolisthesis (18,44,60,90).

The historical cohort study of spinal fusion using pedicle screw fixation reported by Yuan et al. (124) involved a retrospective, multicenter study of 2,684 patients with degenerative spondylolisthesis. Solid radiographic fusion was noted in 89% of patients undergoing pedicle screw fixation compared with 70% of those without instrumentation. Clinical outcome was also better in the group of patients undergoing instrumented fusion.

Nork et al. (65) reported a retrospective study of 30 patients undergoing decompression and instrumented fusion for degenerative spondylolisthesis. Outcome was determined by fusion rate, a functional questionnaire, and the SF-36 survey. Both the rate of fusion and patient satisfaction was 95%. Thirteen patients (43%) had complications, including dural tears (three patients), excessive blood loss (two patients), pseudarthrosis (two patients), pulmonary embolus (PE) (one patient), deep infection (one patient), urinary tract infections (3 patients), and unstable angina (one patient).

A recent randomized prospective study of posterolateral lumbar fusion, with and without pedicle screw instrumentation, for a variety of conditions concluded that the addition of instrumentation did not produce an incremental clinical benefit to that obtained from noninstrumented fusion, although there was a slight nonsignificant trend toward a higher fusion rate in the instrumented fusion group (34). This study, involving a mean clinical follow-up of 40 months, prospectively examined 71 patients undergoing posterolateral fusion for either failed back surgery syndrome (FBSS), degenerative disc disease, isthmic spondylolisthesis, or degenerative spondylolisthesis. For the 10 patients who had degenerative spondylolisthesis, 5 underwent instrumented fusion and 5 underwent fusion in situ. Eighty percent of the patients with degenerative spondylolisthesis undergoing instrumented fusion achieved an excellent or good outcome, compared with 40% of those without instrumentation. For the small subgroup of 10 patients with degenerative spondylolisthesis, the clinical outcome appeared to be better than that of the overall population studied, although this subgroup was too small to establish statistical significance.

There does not appear to be a clear consensus as to the optimal way to treat the patient with degenerative spondylolisthesis. Most studies suggest that patients undergoing concomitant fusion do better when decompression is accompanied by fusion (44). It is less clear, however, whether or not the fusion should be augmented with instrumentation (32). It would seem reasonable that if there is clear evidence of instability on flexion-extension radiographs, the immediate stability provided by instrumentation would warrant the additional time, expense, and potential morbidity associated with its use. On the other hand, the indication for its use in the patient with a collapsed disc space and no motion at the spondylolisthetic level is less clear.

AUTHOR’S PREFERRED TREATMENT

As noted earlier, the optimal surgical treatment of spinal stenosis, particularly when it is associated with degenerative spondylolisthesis, is still somewhat controversial. One area of controversy is the recommended extent of surgical decompression. Because spinal stenosis is a global degenerative condition, there are frequently many symptomatic levels showing radiographic central stenosis, with bilateral foraminal stenosis also being common. Clearly, decompression of every level showing any degree of radiographic stenosis is not always required. Obviously, all symptomatic levels should be decompressed. The extent of surgical decompression of asymptomatic levels, however, depends on many factors. As described earlier, many long-term studies suggest that restenosis at previously decompressed levels, or the development of symptomatic stenosis at previously nonoperated stenotic levels, is a common reason for failure of surgery for spinal stenosis. Therefore, when in doubt, it is generally more prudent to decompress a suspicious segmental level than to decompress. I generally decompress all moderately and severely stenotic levels. When diffuse degenerative changes produce moderate or severe multilevel stenosis, I prefer to decompress the involved levels by unilateral or bilateral laminotomies, rather than by complete laminectomies. This approach reduces the need for concomitant fusion, and it preserves the uninvolved laminae and ligamentous structures, thereby and minimizing the risk of developing late instability.

During the course of surgery, it is sometimes unclear to the surgeon whether or not to decompress an adjacent level above or below the operated level. When this occurs, the degree of central stenosis of the adjacent segment can be gauged by passing a small catheter proximally or distally beneath the laminar. Difficult passage of the catheter mandates decompression of the involved level.

The decision of whether or not to perform fusion on a patient with stenosis associated with degenerative spondylolisthesis can be difficult in the elderly patient with multiple comorbidities. As noted previously, many studies suggest that patients have better clinical outcomes when decompression is accompanied by arthrodesis. The issue of whether or not to augment the fusion with segmental (pedicle) instrumentation is not yet resolved (32,34,125). The decision to fuse must be balanced against the increased morbidity associated with arthrodesis in the elderly patient (29). In the younger, healthy patient with spinal stenosis associated with degenerative spondylolisthesis, I will generally fuse the isthmic level, usually with segmental fixation. In elderly, debilitated, or low-demand patients, arthrodesis may not be required. This is particularly true when the isthmic level is associated with decreased disc height, spur formation, subchondral sclerosis, or ligament ossification. These degenerative changes may help stabilize the isthmic level and minimize the risk of slip progression. Under such conditions, I consider unilateral or bilateral laminotomies in order to preserve uninvolved stabilizing structures.

There are several techniques for orienting the pedicle screws for segmental fixation (Fig. 147.31). Roy-Camille et al. (99,100) described a straight-ahead method, in which the entry point of the pedicle screw is at the junction of a line bisecting the transverse axis of the transverse process and a line bisecting the facet joint (Fig. 147.34). The pedicle screw is oriented parallel to both the sagittal plane and the superior and inferior vertebral end plates. Another technique is the inwards method described by Magner (72,73), in which the pedicle screw entry point is slightly more lateral than that described by Roy-Camille. The entrance point is at the junction of a line intersecting the transverse axis of the transverse process and a line along the lateral aspect of the facet joint (Fig. 147.36). The screw orientation is parallel to the superior and inferior vertebral end plates but is oriented medially so that it is oblique to the sagittal plane.
Postoperative Complications
